Amongst all these, smoke inhalation injury needs explanation. If the fire accidents occur in closed places or in a mass casualty, where there are less chances of  $O_2$  in the atmosphere due to dense smoke, smoke inhalation injury occurs. Products of combustion when plastic products or upholstery gets burnt, they emit a smoke consisting of two deadly chemical compounds namely hydrogen cyanide and CO. These obnoxious gases enter the blood stream instantaneously when the fire occurs in a closed room. CO binds to cardiac myoglobin which results in marked reduction in myocardial oxygen utilization.

Hydrogen cyanide causes tissue asphyxiations through the inhalation of intracellular cytochrome oxidase. This blocks the final step in oxidative phosphorylation and prevents mitochondrial oxygen use. Early diagnosis of the pulmonary injury is essential for survival and is primarily clinical. Primary surgery and energetic treatment with pediatric intensive care unit (PICU) is vital. As soon as the diagnosis is made, the child should be ventilated. The mortality is very high in children with inhalation burn injury.

### BURN WOUND INFECTION

#### Microbiology

Initially burn wounds are sterile but very quickly they become colonized. Subsequently, noninvasive wound infection develops and may progress into invasive sepsis. Limited infection with purulent discharge underneath a burn eschar invades the surrounding normal tissues. Bacteremia causes sepsis and ultimately damage to several organ systems. The prevalence of bacteria differs between burn units. The organisms observed at our center are summarized in **Table 2**. The types of organisms and the seasonal variation are all dictated by the location of the burn unit, city and country. In Chennai, the most prevalent microorganism was *Pseudomonas* (**Figs 5A to C**). Some cultures were found to be extended spectrum  $\beta$ -lactamase-producing types, which are difficult to treat. In spite of adequate treatment, resistant strains do develop.

**Table 2** Microorganism cultures from burn wounds

Gram-negative	<i>Pseudomonas aeruginosa</i> , <i>Klebsiella</i> , <i>E. coli</i> , <i>Acinetobacter</i> spp.
Gram-positive	<i>Staphylococcus aureus</i>
Fungus	<i>Candida</i> spp.

#### Clinical Staging of Burn Wound Infection

Regular monitoring of burn wounds allows early recognition of infection. The American Burn Association recently published criteria for the diagnosis of sepsis and wound infections. Local signs include conversion of a partial-thickness injury to full-thickness wound, worsening cellulites of surrounding normal tissues, eschar separation, and tissue necrosis. The various stages of burn wound infection include wound colonization, wound infection, invasive infection, cellulites, and necrotizing infection/fasciitis.

#### Burn Wound Colonization

Wound colonization is characterized by the presence of low concentrations of bacteria on the surface without invasion or systemic signs or symptoms of infection. Tissue biopsies obtained from colonized but not infected skin usually reveal less than  $10^5$  bacteria per gram of tissue.

**Figures 5A to C** Various manifestations of *Pseudomonas* infection. Origin is from IV line site

### Noninvasive Infection

Wound infection is associated with higher concentration of bacteria ( $> 10^5$  bacteria per gram of tissue) within the wound or wound eschar.

### Invasive sepsis

An invasive infection includes concentrations of bacteria (frequently  $> 10^5$  bacteria per gram of tissue) at an appropriate depth of the burn wound to cause supportive separation of the eschar or graft loss with involvement of unburned tissue or the presence of a systemic response consistent with sepsis.

### Sepsis

The word *sepsis* used in association with burn wounds indicates burn wound infection. An exaggeration of this status defines *severe sepsis*, which is indicative of deep invasion that can rapidly progress into septic shock and has traditionally been defined as sepsis plus multiple organ dysfunction syndrome (MODS). Systemic manifestations of sepsis are the same as those for systemic inflammatory response syndrome.

In children the transition from sepsis to severe sepsis is brisk and very difficult to identify. Following careful and rapid assessment, we have included both stages into one and children were managed aggressively whenever the early signs of wound sepsis were identified. Sepsis is a presumptive diagnosis. Antibiotics are usually started and a search for the cause of infection is initiated. Pathognomonic signs and symptoms include the following:

- Temperature more than  $39^{\circ}\text{C}$  or less than  $36.5^{\circ}\text{C}$
- *Progressive tachycardia*: In children less than 2 SD above age-specific norms
- *Progressive tachypnea*: In children more than 2 SD above age-specific norms
- *Thrombocytopenia*: In children less than 2 SD below age-specific norms
- Hyperglycemia
- Inability to continue enteral feedings more than 24 hours.

To confirm the diagnosis a documented infection must be identified from a culture, pathological tissue, or by a clinical response to antimicrobials.

### Septic Shock

Rapid systemic spread of infection will lead the child to the next phase of septic shock. The child appears very sick with high temperature and MODS, acute respiratory distress syndrome, pneumonia, and reduced urinary output necessitating PICU care. Indicated investigations include complete blood count, serum proteins, wound culture (surface swab, tissue biopsy), blood

culture, and serum procalcitonin level. Samples for culture are taken on admission, at 7 days, and at weekly intervals thereafter. In the presence of sepsis and septic shock, if blood cultures are positive, repeat cultures are done after the antibiotic regimen is completed.

### Treatment of Infectious Complications

#### Antibiotic Administration

As soon as a child with more than 10% TBSA burn is admitted, an immediate surface swab is taken for Gram stain and culture sensitivity. Prophylactic antibiotics are not given except at the extreme of ages or in case of smoke inhalation injury. Aggressive therapy is initiated whenever early signs of wound sepsis are identified. Initial choice of antibiotics is based on the Gram stain and the known sensitivity of the local microbial flora. Subsequently, antibiotic therapy is adjusted according to the culture results.

The initial antibiotic administration for children with burns and sepsis usually includes meropenem and vancomycin. Subsequently, at the conclusion of each antibiotic regimen, repeat cultures, either burn wound surface swab or blood, are done. For children in intensive care unit (ICU) for 5 weeks, surveillance for fungal infection is performed both with blood and catheter tip cultures. If fungal infection is proven, antifungal therapy is also administered.

#### PICU Management of Septic Shock in Burns

Patients are usually admitted to the PICU after a variable period of hospitalization and treatment on a regular ward. As per the approved antibiotic policy, broad-spectrum antibiotics are started immediately, aimed at treating the most common organisms prevalent in our hospital. This usually includes a  $\beta$ -lactam/ $\beta$ -lactamase inhibitor (BL-BLI) such as piperacillin/tazobactam and vancomycin. If the patient has been earlier exposed to BL-BLI combinations, a carbapenem substitute, such as meropenem, is given. In cases of prolonged hospital stay, colistin is usually added to treat *Acinetobacter baumannii*. Antifungal agents to treat *Candida* species, such as amphotericin B or an echinocandin, are also used empirically in patients who have had a prolonged hospital stay and have been exposed to multiple antibiotics. Further antimicrobial therapy is guided by the culture and sensitivity reports. Wounds are grafted only after colony counts from tissue cultures have decreased to acceptable levels. Sometimes during therapy, new microorganisms with different sensitivity patterns may develop. Moreover, a child may occasionally deteriorate despite antibiotic therapy. This could be due to immune deficiency, burn wound reaching deeper tissues such as bones and tendons, lack of proper debridement of devitalized tissues or microorganisms such as *Staphylococcus aureus* either methicillin-resistant *Staphylococcus*

*aureus* (MRSA) or methicillin sensitive forming a biofilm. A number of biofilms were detected among the MRSA infected group with recurrent infection 5 weeks after apparent recovery. For treatment of such cases, if the isolated microorganism is sensitive to more than one antibiotic, the already used antibiotic may be replaced by another one.

### Fungal Infection

If child has been in PICU with sepsis, after 3 weeks, culture is done and if found positive, antifungal treatment is continued.

## SPECIAL BURNS

### Chemical Burns (Acid, Alkali, Phosphorous, Anemia; Figs 6A to D)

These are most commonly seen to a chemical industry or as part of abuse. The chemical process continues for a longtime after the substance touches the body. Early surgical intervention is not advocated. But the vital areas (eyes) are protected with a tarsorrhaphy or soft lens to save the vision.

### Major Electric Burns (Figs 7A and B)

Major electric burns are seen in high tension electric accidents. These need immediate attention on removal of a lifeless limb. Escharotomies are done liberally, all dead tissue are removed and grafting done. These burns need ICU care.

## MANAGEMENT OF BURN WOUNDS

This varies extensively in various centers but the principle is to identify the depth of burn and extent. Then the survey in vital areas, like the face, eye and oral cavity, are performed. Airway obstructions if any is identified and details have been given earlier. Circumferential burns causing embarrassment to circulation are identified. *Nonsurgical treatment* consists of biological dressings and topical antimicrobials. *Surgical treatment* consists of primary skin grafting, secondary grafting in prolonged and infected case, reconstruction, microsurgery, and tissue expansion.

### Nonsurgical Treatment

#### Topical Antimicrobials

Superficial and superficial partial-thickness burns (**Fig. 8**) even up to 20–30% TBSA can be treated with topical antimicrobials like

silver sulfadiazine. However if any vital areas, like perineum or face, gets infected, appropriate antibiotics are given systematically after wound swab—culture and sensitivity. Circumferential burns and perineal burns would also require closed dressings.

The second degree (superficial partial-thickness burns which are circumferential must get closed dressings. Here there are a lot of topical antimicrobials used by us today. Silver sulfadiazine has been the sheet anchor for the last many years. Newer topical creams also have come in the market. The idea is to prevent infection, particularly in a closed wound, in the tropics. The dressing is changed every other day or even once a day according to soiling of the gauze.

### Collagen Dressing

Superficial and deep partial-thickness burns are treated with biologic dressings particularly collagen (**Figs 9A to E**) which is less labor-intensive and we can observe the progress of the wound daily. In certain special areas, like perineum, scrotum and groin, closed dressings may have to be used, because the membrane gets lost with dressing.

Deep partial-thickness burns need to be observed. If the area is extensive, collagen membrane can be applied (**Figs 10A to E**). But as soon as the wound healing gets delayed the membrane can be removed, excision of the burnt area and autografting should be done.

If signs of sepsis are seen, they have to be treated as per sepsis protocol mentioned earlier. If the wounds need skin grafting after infection settles, it is done as early as possible. Third-degree burns may need primary excision or tangential excision. Grafting priorities in surgical intervention are eyes, face, hands and perineum. At all cost the cornea and lens are protected with tarsorrhaphy or soft contact lens.

## Surgical Management

### Primary Surgery

In over 15% burns, all deep areas are excised and covered with autografting.

### Secondary Surgery

If the child gets into sepsis, after sepsis is cleared (blood culture negative) all the sloughed tissue can be removed and autografting is done. During surgery the child should be supported with appropriate antibiotics.

Figures 6A to D Chemical burns

Figures 7A and B Electric burns

Figure 8 Superficial and superficial partial-thickness burns

### Reconstructions

Final reconstructions like postburn contractures are released and grafted, but one has to realize that as the child grows, repeated surgeries may have to be undertaken. Microsurgical procedures may have to be done, to save the limb and function. Microsurgical free flaps also have been giving very good results in postburn contraction. *Tissue expansion* is sometimes useful for postburn scars.

### Physical Rehabilitation and Splinting

In burns, starting with respiratory physiotherapy in the early

days to limb movement, and postoperative physical therapy and activated splinting also must be planned. This begins on day one of burn to the stage when child can use the part normally.

### IN A NUTSHELL

1. Although burn injuries that cover 25% or more of the BSA are considered as *major burns*, any burn injury more than 10% should be treated similarly.
2. A methodical initial approach to burn treatment includes primary survey, investigations, pain management, secondary survey and focused history, and safe transfer to a specialized burns facility.
3. Assessment of total body burnt surface area in children can be done by Lund and Browder chart.
4. All burns of more than 15% BSA require intravenous fluid resuscitation to maintain adequate tissue perfusion.
5. Regular monitoring of burn wounds is important for early recognition of infection; which needs to be treated aggressively and immediately. Prophylactic antibiotics are not indicated as a routine.
6. *Nonsurgical treatment* consists of biological dressings and topical antimicrobials. *Surgical treatment* consists of primary skin grafting, secondary grafting in prolonged and infected case, reconstruction, microsurgery, and tissue expansion.

## Chapter 10.5

# Cold Injuries

Manu Madhok, Shruti Kant

Cold exposure can produce various injuries in children as a result of limited adaptability to cold stress. Cold injuries can broadly be divided into localized injury to a body part or parts (peripheral cold injuries), generalized cooling of the entire body (hypothermia), or a combination of both. Early recognition and appropriate treatment is imperative for optimal outcome.

### EPIDEMIOLOGY

Frostbite is well documented in the military records and reported in countries with extremes of temperature for centuries. The earliest documented evidence of frostbite dates back to a 5,000-year-old pre-Columbian mummy discovered in the Andes. The first detailed report of multiple cold injuries was by Baron Larrey, surgeon-in-chief to Napoleon's army during the invasion of Russia in the winter of 1812–1813. The epidemiology of cold injuries is not well documented in medical literature from India and SE Asia. However, there are multiple media reports related to cold exposure every year in northern India and Himalayan range. A published case series describes 234 cases of cold injuries in a 2-year period, seen at Army Hospital in Leh, Ladakh. In United States, the Centers for Disease Control and Prevention reports that between 1979 and 2002, a total of 16,555 deaths in the United States (an average of 689 per year; range: 417–1,021) were attributed to excessive natural cold exposure, an annual death rate of 0.2 per 100,000 population. Exact incidence of cold water drowning and accidental hypothermia is unknown, but it is a low frequency event but common in childhood and boys more commonly involved than girls. The data from 1995–2004 National Hospital Ambulatory Medical Care Surveys revealed an estimate of 15,574 visits to *emergency department* related to hypothermia and other cold injuries in the United States.

### ETIOLOGY

Heat loss occurs from the body by radiation, conduction, convection, evaporation, and respiration. Children are at a higher risk for cold-related injuries and hypothermia than adults because of a smaller ratio of body mass to surface area, leading to increased heat loss; decreased ability to recognize or avoid dangerous environmental conditions; limited glycogen stores in young children to support increased heat production and the inability to increase heat production through shivering in infants. **Table 1** summarizes the risk factors for hypothermia. However, young children have an advantage of neuroprotective effect and more likely than adults to have good neurologic outcomes, despite severe or profound hypothermia. Prolonged cold exposures and temperatures below freezing point produce peripheral cold injuries. The extent of injury is proportional to the exposure and range from frostnip, to chilblains, to immersion foot, to frostbite. The infants or young children are at greater risk because of immobility and higher surface area-to-mass ratio (children) but frostbite is seen more commonly in young adults between the ages of 30 years and 49 years, most likely due to increased exposure to cold or risk-taking behavior. It is also increasing within the civilian population from participating in winter sports such as skiing, hiking, mountain and ice climbing with limited experience or inadequate preparation and protection.

**Table 1** Risk factors for hypothermia

Child-specific	Predisposing	Environmental factors
Large body surface area relative to mass leading to excessive heat loss	Underlying medical conditions, malnutrition	Extreme cold temperatures
Lack of glycogen stores and shivering capability in infants	Lack of education/awareness about appropriate clothing	Wind chill
Lack of cognitive skills for seeking shelter	Use of intoxicating substance and risk taking behavior	Wet cold conditions
Lack of supervision by caregivers	Improper storage of chemicals and not using protective equipment	Sudden weather changes

### PERIPHERAL COLD INJURIES

#### Frostnip

Frostnip is the mildest form of peripheral cold injury and involves acral areas like nose, ears, hands, and feet. Frostnip is caused by prolonged exposure to cold air in the exposed body parts like in skiers and children standing outside waiting for school bus. It presents as erythema and pain, like a first-degree burn, numbness, itching or burning sensation in hands, feet, toes, fingers, face, nose and ears. Simple warming either by pressure of a warm hand or by placing the hand in the axilla or wrapping in a warm clothing is sufficient treatment.

#### Chilblain (Perniones)

Chilblain represents a more severe form of cold injury than frostnip. It also occurs after exposure to nonfreezing temperatures and damp conditions. The etiology is idiopathic and auto-immune in some cases and precipitated by cold exposure and moisture. The surface of unprotected extremities, such as the hands, feet, and face develop capillary bed damage and show red-to-violaceous raised lesions of vasculitis. Blisters, erosions, or ulcers are sometimes seen. The lesions usually resolve spontaneously in 1–3 weeks, but they may recur in some individuals (Raynaud's phenomenon). Management involves local heat, gentle massage, and moisturizers to keep the skin supple. Nifedipine may be used to reduce the pain and speed the healing of the lesions.

#### Immersion (Trench) Foot

Immersion foot or trench foot is a disease of the sympathetic nerves and blood vessels in the feet. It is mostly seen in persons whose feet have been wet, but not freezing, for prolonged periods. The symptoms include numbness and tingling pain with itching, progressing to leg cramps and complete numbness. Initially, the skin is red, it becomes progressively pale or blotchy and then cyanotic. The progression of this cold injury has three stages. The first is a prehyperemic phase, lasting for a few hours to a few days, in which the limb is cold, slightly swollen, discolored, and possibly numb. Major pulses are barely palpable. The second, or hyperemic phase, lasts 2–6 weeks. It is characterized by bounding, pulsatile circulation in a red, swollen foot. The third, or posthyperemic, phase can last for weeks or months. The limb may be warm, with increased sensitivity to cold. The injury often produces a superficial, moist gangrene.

Management of this injury involves gentle washing and air-drying of the feet, slow rewarming, bed rest, and slight elevation

of the extremity. Improvement occurs within 24–48 hours, but may take 1–2 weeks to resolve completely. Early physical therapy is crucial. The patient should be forewarned that subsequent cold exposure will preferentially affect the previously injured area.

## FROSTBITE

Frostbite is a freezing, cold thermal injury, which occurs when tissues are exposed to temperatures below their freezing point (typically  $-0.55^{\circ}\text{C}$ , but can occur at as high as  $2^{\circ}\text{C}$  for a sustained period of time. Severity of injury depends on factors such as absolute temperature, wind chill, duration of exposure, wet or dry cold, immersion, clothing quality and patient comorbidities such as smoking, peripheral vascular disease, neuropathies, Raynaud's disease, mental health issues, alcohol and substance abuse and dementia. The risk of frostbite is correlated with ambient temperature and wind speed contributing to wind chill. This is likely when temperature (includes wind chill) drops to less than  $-20^{\circ}\text{C}$  ( $-4^{\circ}\text{F}$ ).

## Pathophysiology

The pathophysiology of frostbite can be described in four overlapping pathologic phases: prefreeze, freeze-thaw, vascular stasis, and a later ischemic phase. In the initial pre-freeze state, there is a considerable decrease in blood flow because of skin cooling and vasoconstriction. This does not involve the formation of actual ice crystals. Next, in the freeze-thaw phase, there is intra or extracellular ice crystals formation leading to protein and lipid derangement, cellular shifts of electrolytes and endothelial cell damage. The thawing process brings about ischemia-reperfusion injury and the inflammatory response. There is a release of prostaglandin F<sub>2</sub> and thromboxane A<sub>2</sub> causing platelet aggregation and vasoconstriction. After tissue thawing, in the vascular stasis phase, vasodilation and leakage from capillaries occur, causing tissue edema. Alternating freeze-thaw cycles potentiate the vascular injury and lead to ischemia. Finally, in the later ischemic phase of frostbite, there is tissue ischemia and infarction due to an inflammation response, intermittent constriction of arterioles and venules, and a continued reperfusion injury. Tissue necrosis that follows frostbite is due to either cellular injury or secondary to a vascular lesion.

## Clinical Features

The hands and feet are affected in over 90% of injuries. The injuries have been classified in grades to help with management. Commonly used classification grades frostbite injury into two types: superficial or deep. Superficial frostbite (first- and second-degree frostbite) involves the skin and subcutaneous tissues. The skin feels cold, waxy white, and does not blanch. The frozen part is numb but becomes painful and flushed with thawing. Within the first 24 hours, edema develops and blisters or bullae filled with serous fluid appear (**Fig. 1**). Deep frostbite (third- and fourth-degree frostbite) involves the deeper tissues of muscle, tendons, neurovascular structures, and bone, along with the skin and subcutaneous tissues. The frozen part is hard, numb and appears gray-blue, or mottled. It remains unchanged even after rewarming. Edema develops over next 24 hours, but bullae may not be present. They may appear later and have hemorrhagic fluid (**Fig. 2**).

## Approach to Diagnosis

Patients with frostbite frequently have associated multisystem injuries like systemic hypothermia, blunt trauma, alcohol or substance abuse, etc. The health-care providers should obtain a detailed history of exposure and comorbid conditions to determine associated injuries and appropriately treat most

**Figure 1** Frostbite superficial (second degree)

Source: Hota PK, Singh KJ. Management of cold injuries. Surgical Research Updates. 2013;1:20-25.

**Figure 2** Frostbite deep (third degree)

Source: Hota PK, Singh KJ. Management of cold injuries. Surgical Research Updates. 2013;1:20-25.

life-threatening injuries first. Accurate vital signs with core temperature determination and clear description of injury using standard anatomic terminology are important. Taking pictures of lesions help with monitoring progression and minimize tissue manipulation when multiple providers need to evaluate the injury. Imaging and laboratory tests are helpful in identifying associated injuries.

## Management

### Prehospital

The patient must be removed from cold environment. All cold and wet clothing or boots, etc., must be removed. The affected areas should be immobilized and covered with dry clothing, socks and gloves. One can attempt to warm the cold extremity by placing it in a companion's armpit or groin for 10 min but rubbing or massage should be avoided. Removal of jewelry from affected digits can be attempted. Field rewarming should only be attempted if there is no further risk of refreezing as tissue that thaws then refreezes results in more extensive injury.

## Hospital

Patient should be re-evaluated on arrival to a hospital and any associated trauma or hypothermia must be assessed and managed before frostbitten extremities are treated. Moderate or severe hypothermia should be corrected to bring core temperature above 35°C before initiating frostbite warming. Tetanus prophylaxis, aspirin, pentoxifylline and ibuprofen for antiplatelet, rheologic and prostaglandin effects, and pain control with narcotics, hydration with warm fluids should be addressed.

## Rewarming

Hot water bath at 39–42°C (102.2–107.6°F) is recommended for rewarming with attention to aseptic techniques and close monitoring of water temperature. The frostbitten tissue is removed when it appears flushed indicating return of perfusion. It may take 30–45 min. Active movement of frostbitten area is encouraged to assess tissue pliability. After cleansing of tissue and wounds, a dry dressing and splinting is recommended. Debridement of blisters is still controversial. For deep frostbite (third- and fourth-degree), antibiotic prophylaxis is recommended and hyperbaric oxygen therapy if often utilized. Imaging with angiography, magnetic resonance angiography and technetium-99 (99Tc) triple phase bone scanning help visualize vascular occlusion and demarcation of ischemic area. This is helpful in prognosis and directing surgical therapy or thrombolytic therapy. Published studies to evaluate the safety and efficacy of tissue plasminogen activator (rTPA) in the treatment of severe frostbite found that rTPA and heparin after rapid rewarming is safe and reduced predicted digit amputations, especially when initiated within 24 hours.

## Complications and Long-Term Effects

Compartment syndrome may require fasciotomy. It may take 6–12 weeks for demarcation of ischemic tissue, which may lead to amputation. Localized osteoporosis and subchondral bone loss may be seen and is of significance in children as the damage may lead to undergrowth of affected bone and development of early arthritis. Chronic regional pain is a common sequel after frostbite. The tissue after recovering from frostbite is more susceptible to subsequent freezing injury. The patients should be educated about this risk and cold sensitivity.

## HYPOTHERMIA

Hypothermia is defined as a core body temperature below 35°C (95°F). Hypothermia in children is easy to overlook but significantly impacts optimal management of underlying disease. The degree of hypothermia, defined by core temperature, influences both recognition and treatment. When reliable and precise measurement of temperature is difficult, hypothermia may be determined clinically with the use of the Swiss staging system. The definitions for staging of hypothermia are given in **Table 2**.

**Table 2** Staging of hypothermia

Degree	Temperature	Clinical findings per Swiss staging system
Mild (Hypothermia I)	Core temperature 32–35°C (90–95°F)	Impaired consciousness, shivering
Moderate (Hypothermia II)	Core temperature 28–32°C (82–90°F)	Impaired consciousness, not shivering
Severe (Hypothermia III)	Core temperature below 28°C (82°F)	Unconscious, not shivering, vital signs present
Profound (Hypothermia IV)	Core temperature below 20°C (68°F)	Unconscious, vital signs absent

## Pathophysiology

The physiologic changes in hypothermia include the following:

- Respiration progressively becomes slow, shallow, irregular, and then absent.
- Blood volume markedly decreases causing hypovolemia. This is because of vascular leak and a *cold diuresis* secondary to inhibition of antidiuretic hormone and failure of distal tubular sodium and water reabsorption.
- Cardiac output is reduced by hypovolemia, sludging of blood due to cold, decreased myocardial contractility, and bradycardia. Also, loss of vasomotor regulation causes vasodilation and lowers systemic vascular resistance. All of these factors lead to circulatory collapse.
- Hypothermia increases myocardial irritability, making ventricular fibrillation (VF) a frequent problem in severe hypothermia. Potential risk factors for VF include rough handling of patient or patient exertion, core temperature afterdrop (further cooling of the body after being removed from cold exposure), room-temperature fluids administration, direct stimulation of the myocardium (central lines, and rewarming shock).
- Other effects of hypothermia may include thrombocytopenia, coagulopathy, hyperkalemia, hypoglycemia or hyperglycemia, and metabolic acidosis or alkalosis.

## Pathological Characteristics and Clinical Features

Physiologic and pathologic changes in body correspond to the stage of hypothermia. In *mild hypothermia*, the body copes with heat loss by shivering, vasoconstriction, and an increased metabolism. Mentation and consciousness are preserved. In *moderate hypothermia*, these compensatory mechanisms begin to fail and manifested by lack of shivering, respiratory depression, decrease in metabolism, circulatory compromise, vasodilation and altered consciousness, including lethargy, confusion, and possible *paradoxical undressing* or other irrational behavior. In *severe hypothermia*, patients usually become unconscious and vital signs may or may not be present. Muscle rigidity develops. The risk of cardiac arrest increases as the core temperature drops below 32°C and increases substantially if the temperature is less than 28°C. At 28°C (82°F) the basal metabolic rate is approximately half of the normal rate and all body functions begin to fail including circulation, ventilation, and central nervous system function.

## Differential Diagnoses (Box 1)

Hypothermia may occur from environmental exposure, trauma, medical conditions, or a combination of these.

## Trauma

It is important to measure core temperature during resuscitation and efforts should be taken to prevent heat loss. Hypothermia is caused by exposure or injury, during transport and resuscitation, especially in infants and young children with larger body surface. It is often seen when environmental exposure is prolonged (e.g., motor vehicle accidents in winter with difficult extrication). Patients with traumatic brain injury or spinal cord injury are also at risk for hypothermia because of potential damage to central and autonomic thermoregulatory systems.

## Medical Conditions

Medical conditions often produce mild hypothermia. Common etiologies associated with hypothermia in children include sepsis, hypoglycemia, hyponatremia, central nervous system pathology (e.g., craniopharyngioma, absence of the corpus callosum, intracranial bleeding), endocrine disease (e.g., hypothyroidism or adrenal insufficiency), malnutrition, anorexia nervosa and burns.

**BOX 1 Differential diagnoses of hypothermia**

- *Trauma*
  - Burns
  - Drowning
  - Intracranial hemorrhage
  - Traumatic brain injury/spinal cord injury
- *Infections*
  - Sepsis
  - Meningitis/encephalitis
- *Drug overdose*
  - Ethanol
  - Barbiturates
  - Benzodiazepines
  - Clonidine
  - Antidepressants
  - Antipsychotics
- *CNS pathology*
  - Stroke
  - Brain tumors (craniopharyngioma) and congenital malformations
  - Dysautonomia
- *Metabolic/endocrine*
  - Hypoglycemia
  - Adrenal insufficiency
  - Hypothyroidism
  - Hypoparathyroidism
  - Aminoacidemia
  - Organic acidemia.

**Sepsis**

Sepsis may present as mild hypothermia, especially in young infants and older children with chronic medical conditions or immunosuppression. These patients appear sick with lethargy, hypotension, widened pulse pressure that cannot be explained by mild hypothermia.

**Drug Overdose**

Drug overdose and toxins that may cause vasodilatation and altered mental status lead to hypothermia. Overdose of ethanol, benzodiazepines, opioids, clonidine, atypical antipsychotic medications and cyclic antidepressant medications are associated with hypothermia. It is often seen in adolescents who may become disoriented or pass out after a recreational drug use in an outdoor setting and then become hypothermic.

**Approach to Diagnosis****Prehospital Care and Triage**

Prehospital providers and medical control physicians should have a high suspicion for hypothermia in children with obvious environmental exposure and in children with altered mental status or those needing critical care. Patients should be extracted from the cold environment in a horizontal position, if possible. Prehospital providers should try to minimize further heat loss, avoid excess manipulation or patient exertion during transport as it may cause mobilization of cold and acidic blood to the heart and trigger cardiac arrhythmias or instability. Key interventions include:

- Removal of wet clothing
- Gentle insulation of the patient with warm blankets or other items (sleeping bag)
- Warming of the transport vehicle
- Provision of warm intravenous (IV) fluids.

Children with moderate hypothermia need transport to a hospital with pediatric intensive care capability. The patients with severe hypothermia should undergo transport to a hospital with active rewarming or cardiopulmonary bypass facilities like Level I designated and pediatric trauma centers.

**Hospital Care**

Standard pediatric advanced life support (PALS) and advanced trauma life support (ATLS) protocols should be followed with attention to airway, breathing, circulation, disability and exposure. Administration of heated, humidified oxygen is an acceptable therapy for all hypothermic patients.

**Investigations**

No laboratory testing is required for previously healthy children with mild hypothermia from environmental exposure. However, in patients with moderate to severe hypothermia, several laboratory parameters may be altered, and the following studies should be obtained: serum glucose, serum electrolytes, lactate, complete blood count, coagulation studies, blood type and cross match (if the need for extracorporeal warming is anticipated) and blood gas analysis. Capillary samples may be unreliable for measuring acid-base balance because of poor perfusion.

**Electrocardiogram**

Hypothermic patients should have a 12 lead electrocardiogram (ECG) and then placed on a cardiac monitor during treatment. The development of ventricular fibrillation, pulseless electrical activity (PEA), or asystole are common during resuscitation during hypothermia. Hypothermia slows impulse conduction through potassium channels leading to prolongation of RR, PR, QRS, and QT intervals. There may also be elevation of the J point, producing a characteristic J or Osborn wave (**Fig. 3**). Tomaszewski originally described the J wave in 1938 as a very slow inscribed deflection between QRS complex and ST segment, however, its clinical significance was described in acidotic and hypothermic dogs by Osborn in 1953.

**Management**

The accurate measurement of core body temperature in children with hypothermia is essential to proper treatment. Successful resuscitation of the hypothermic child requires rapid attention to supportive care (airway, breathing, circulation), assessment and treatment of injury or other medical conditions, and rewarming interventions, that vary based upon core body temperature and the presence or absence of circulation.

**Airway and Breathing**

Warmed, humidified 100% oxygen [41–45°C (105.8–113°F)] via nonrebreather mask is delivered. Bag-valve-mask ventilation is reserved for children with hypoventilation and when preparing for endotracheal intubation. Endotracheal intubation is indicated in respiratory failure, uncompensated shock, or cardiac arrest.

**Circulation**

Patients with nonperfusing rhythms (asystole, PEA, VF, ventricular tachycardia without pulse) should receive chest compressions using standard rates and depths per PALS guidelines. Bedside ultrasound may be useful in assessing cardiac contractility. Sinus bradycardia, first-degree AV block, and atrial fibrillation with slow ventricular response may improve with adequate oxygenation. Cardiac pacing generally is required only if bradycardia persists despite rewarming to 32–35°C (90–95°F). The medications for bradycardia (e.g., atropine, epinephrine) may not be necessary because perfusing bradycardic rhythms usually convert to sinus rhythm with rewarming.

**Vascular Access and Intravenous Fluid Therapy**

Cold-induced vasoconstriction makes vascular access difficult, however, vascular access and aggressive volume expansion are a vital treatment for moderate and severe hypothermia. Two peripheral

**Figure 3** ECG changes in hypothermia

[Source: Chhabra L, Devadoss R, Liti B, Spodick DH. Electrocardiographic changes in hypothermia: a review. *Ther Hypothermia Temp Manag.* 2013;3:54-62.]

IV catheters (22G or bigger) should be placed for adequate access. Intraosseous needle access or central line via the femoral vein should be the next step, if peripheral access is not established.

### Warm Fluids

These patients should initially receive 20 mL/kg of heated (40–44°C) IV normal saline using high-capacity in-line warmers via rapid IV infusion methods.

### Active External Rewarming

Active external rewarming uses heating devices like radiant heat, forced hot air, warm blankets or heating pads, warm bath water, infrared heating lights or heated devices (warm packs). They should be applied to the trunk to warm the core. Active external rewarming is recommended for mild to moderate hypothermia and should be avoided for severe hypothermia.

### Active Core Rewarming

Active internal rewarming techniques are utilized for patients with moderate to severe hypothermia with core body temperature less than 30°C (86°F). This includes administration of warmed humidified oxygen, IV administration of warmed saline, peritoneal or pleural lavage and the use of extracorporeal membrane oxygenators. Left pleural lavage with heated normal saline is a preferred active internal rewarming method and is performed by placing two chest tubes in the left pleural cavity with inflow via anterior and drainage via posterior tube. Heated fluid instilled through the anterior chest tube directly warms the heart. No randomized, controlled clinical trials have been reported comparing the efficacy of these methods.

### Extracorporeal Techniques

Extracorporeal techniques include cardiac bypass and extracorporeal membrane oxygenation (ECMO) are suggested

for children with severe hypothermia and absent circulation or in patients' refractory to other techniques. Warming by cardiopulmonary bypass is the most efficient method of core heating. **Table 3** summarizes the guidelines for the management of hypothermia.

### Outcomes

Rewarming shock is a major risk of active external rewarming. Cold, acidic blood that returns to the core circulation causes a drop in temperature and pH. Rewarming shock can be life-threatening if rewarming is not accompanied by vigorous support of shock. During rewarming, significant hyperkalemia may develop especially after sustained crushing injuries.

Prediction of neurologic outcome based on physical examination in hypothermic children may be misleading. Because of the neuroprotective effects of hypothermia, the severely hypothermic child may still have good outcome. Also, prolonged intensive support (e.g., up to 5 days of ECMO) has been associated with good outcomes. Prognostic scoring systems, such as the Glasgow Coma Scale, have not proved useful for hypothermic patients, but extreme acidosis (pH < 6.6), hyperkalemia (initial K<sup>+</sup> level > 8), and lactate more than 225 mg/dL, are associated with poor outcome.

### Prevention

Hypothermia can be prevented by limiting exposure to extreme cold temperatures and using proper protection by dressing warmly and wearing layers, and changing out of wet clothes as quickly as possible. Babies and young children are more likely to get hypothermia and should wear hats and mittens in cold weather. Children should take a break to warm up while playing outside in the cold. Alcohol intoxication in adolescents is a high-risk factor for getting hypothermia. Alcohol and other chemical or drug abuse should be avoided when engaging in outdoor winter recreational

**Table 3** Management guidelines for hypothermia

<i>Prehospital</i>	<i>Hospital</i>
Quick and safe extrication	Assess patient per ATLS and ACLS guidelines
Quick assessment of ABC and initiate CPR, if needed	ABCDE and continue CPR Obtain accurate core temperature and monitor, external rewarming measures
Quick assessment of degree of hypothermia and associated injuries for appropriate transport/transfer	Warm, humidified air via patent natural airway or secure endotracheal tube
Removal of cold/wet clothing and cover with warm/dry clothing	Warm intravenous fluids via large peripheral IV or intraosseous or central access to correct for shock
Stabilize patient with minimizing tissue manipulation	Identify and correct metabolic and other medical or traumatic conditions with appropriate labs, EKG and imaging
Minimize further heat loss	Aggressive internal warming
Notification and transport to appropriate receiving facility	Consider cardiac bypass or ECMO support per institutional capability and protocols

*Abbreviations:* ATLS, advanced trauma life support; ACLS, advanced cardiac life support; ABCDE, airway, breathing, circulation, disability and exposure; CPR, cardiopulmonary resuscitation; ECMO, extracorporeal membrane oxygenation.

activities. Secondary hypothermia in patients with sepsis and trauma can be prevented by close monitoring of body temperature, minimizing exposure and utilization of warm IV fluids and warm humidified air.

### IN A NUTSHELL

1. Children are at greater risk for hypothermia because of their small body mass relative to surface area; prevention by adequate protective clothing is important.
2. In prehospital settings where obtaining an accurate core temperature measurement is difficult, the degree of hypothermia can be estimated from clinical findings.
3. The accurate measurement and monitoring of core body temperature are essential to proper diagnosis and management.
4. Patients with severe hypothermia and absent vital signs should not be considered dead until they are near normal core temperature and are unresponsive to cardiopulmonary resuscitation.
5. Because of the neuroprotective effects of hypothermia, the severely hypothermic child may still have potential for intact survival with proper resuscitation.
6. Medical conditions can result in hypothermia in children and should be considered when hypothermia is resistant to rewarming (e.g., sepsis, hypothyroidism, adrenal insufficiency).
7. Children with severe hypothermia (core temperature < 28°C) and absent circulation should be considered for extracorporeal methods like cardiac bypass or extracorporeal membrane oxygenation, if available.

### Chapter 11.1

### Fetal Physiology and Growth

Deepak Chawla

Starting with a single cell fertilized ovum, an embryo develops by the process of cellular division, differentiation and maturation into a complex organism with different organ systems performing specialized functions. This rapid growth is driven by inherent genetic make-up of the fetus and is influenced by intrauterine environment, transplacental provision of nutrients and exposure of mother to various environmental agents.

After fertilization in the fallopian tube, the ovum undergoes a series of mitotic divisions to form 16-celled morula 3 days after fertilization. By the time, embryo enters the uterine cavity it has formed a cavity inside it and is now called blastocyst. Its cells are divided into an inner cell mass and an outer cells mass. Inner cell mass is called embryoblast and forms the embryo proper. Outer cell mass is called trophoblast and contributes to formation of placenta. Under effect of progesterone, uterine endometrium is in secretory phase and is ready for implantation of the embryo. During second week after fertilization, blastocyst is embedded in the uterine endometrium. Trophoblast differentiates into inner proliferating cytotrophoblast which start forming the placental villi and outer syncytiotrophoblast which invades the uterine endometrium. By end of second week, maternal blood enters the lacunar network formed by syncytiotrophoblast and uteroplacental circulation begins. Third week of development called gastrulation is characterized by formation of three germ layers: endoderm, mesoderm and ectoderm. Cephalic and caudal ends and laterality of the embryo is also established during this phase. Teratogenic influence of toxic agents such as alcohol, maternal hyperglycemia due to diabetes or intake of drugs can effect development of the germ layers leading to birth defects such as holoprosencephaly, caudal dysgenesis and situs inversus (**Table 1**).

Third to eighth week of development, known as embryonic period, is the time of organogenesis when the three germ layers give rise to different organ systems. On dorsal aspect of the embryo, neural plate is formed by ectoderm. Neural plate forms the neural folds which fuse to form the neural tube. Closure of the neural tube starts in the cervical region and proceeds in cephalic and caudal direction so that cranial end of the neural folds is closed on 25th day and caudal end is closed on the 28th day of fertilization. Cranial portion of the neural tube forms the brain vesicles and caudal portion of the neural tube forms the spinal cord. Incomplete closure of the neural tube can result in neural tube defects such as anencephaly and spina bifida. In addition to central nervous system, ectodermal germ cells give rise to peripheral nervous

system, skin and sensory epithelium of ear, nose and eyes. On ventral side of the embryo gut, tube is formed and starts increasing in length. Lateral body folds fuse to form the body cavity. Body cavity is divided into thoracic and peritoneal cavities by diaphragm which closes the pleuroperitoneal canal. Failure of closure of the ventral body folds can lead to ventral wall defects while failure of the pleuroperitoneal canal results in congenital diaphragmatic hernia (**Table 1**). Mesodermal germ layer of the embryo forms the somites which form the muscles, bone, cartilage and dermis. Heart, blood vessels, blood cells, urogenital system and spleen are also formed from the mesoderm. Endoderm germ layer gives rise to epithelial cells layers of the gastrointestinal and respiratory tracts, thyroid, parathyroid, liver and pancreas.

During embryonic period, stems cells destined to form main organ systems start dividing and different organs are recognizable by end of the 8 weeks of fertilization. On external examination head forms about half of the length of the embryo and eyes, external ears, upper and lower limbs with digits can be recognized. Due to rapid cell division embryonic period is prone to teratogenic effect of drugs, infections and radiation. Most of major congenital malformations arise in this period.

**Table 1** Abnormalities in the embryonic development

Period of gestation	Abnormality	Clinical consequences
2nd to 3rd week	Abnormal implantation of the embryo	Ectopic pregnancy
	Effect of alcohol, maternal diabetes or other teratogenic drugs on development of germ cells	Holoprosencephaly Caudal dysgenesis Renal agenesis Imperforate anus Situs inversus
3rd to 8th week	Failure of closure of neural tube on dorsal aspect of the fetus	Anencephaly Spina bifida
	Failure of closure of ventral body walls	Ectopia cordis Gastroschisis Bladder exstrophy
	Failure of closure of pleuroperitoneal canal	Congenital diaphragmatic hernia
	Cardiac looping	Dextrocardia
	Formation of cardiac septa	Atrial and ventricular septal defects
		Transposition of great vessels
		Tetralogy of Fallot
	Formation of lung bud	Tracheoesophageal fistula
	Breakdown of anal membrane	Anal atresia

Period from third to ninth month of gestation is called the fetal period. During this period, tissues undergo maturation and increase in cell size. Structure and function of different organ systems are matured. Timeline and major stages of development of the main organ systems are summarized in **Table 2**.

## FETAL NUTRITION AND ENDOCRINE FUNCTION

Fetal period is the most rapid period of growth in whole lifespan. Most rapid increase in fetal length is observed in first 3 months of the fetal period and most rapid increase in fetal weight is observed in last 2 months of the fetal period. Human placenta plays vital role in fetal growth by being the organ of transfer of nutrients from mother to fetus and by synthesizing various hormones which promote fetal growth. Placenta produces growth hormone, insulin-like growth factors (IGF) and human placental lactogen. Peptide hormones including insulin produced by mother cannot cross placenta. Insulin produced by fetus and IGFs from placenta and fetus are main growth promoting hormones of the fetus. These hormones prevent fetal protein breakdown and promote deposition of glycogen in liver and fat in adipose tissue. IGF-2 plays important role in embryonic and early fetal growth. IGF-1 is main regulator of late fetal growth. Mutations in IGF ligands or its receptors lead to intrauterine growth restriction (IUGR). Similarly, mutations resulting in insulin resistance or pancreatic agenesis also cause severe IUGR. Human placental lactogen (HPL) also coordinates transfer of nutrients from mother to the fetus. Along with increase in maternal growth hormone, it produces relative insulin resistance in mother. This results in increased circulating levels of glucose and lipids. HPL also exerts anabolic effect on fetus by increasing levels of IGF-1 and IGF-2 in fetal circulation and decreasing levels of IGF binding proteins.

Glucose is the main energy substrate for fetus and is transferred through carrier-mediated transport (glucose transport proteins (GLUT-1 and GLUT-3)). Glucose transport is driven by downward concentration gradient. If mother is hyperglycemic because of diabetes mellitus more glucose is transported to fetus. Excess glucose left after consumption for energy needs stimulates fetal insulin secretion and is deposited in fetus as glycogen and fat. Therefore babies born to mothers with uncontrolled diabetes are macrosomic and at risk of shoulder dystocia. After birth, maternal continuous glucose supply is removed and the newborn infant is dependent on the stored glycogen till feeding starts. Babies with low glycogen stores because of IUGR or inadequate mobilization of glycogen because of excess insulin secretion (infants of diabetic mothers) are at risk of hypoglycemia in this period of transition and need to be monitored for first 48–72 hour of birth.

Trophoblast plays critical role in transfer of amino acids by uptake from maternal side of placental circulation and then actively transporting them to the fetal side. This is an energy dependent process and decrease in energy substrate supply to the placenta causes decrease in fetal transfer of amino acids and therefore IUGR. This is one of mechanism of IUGR in chronic maternal hypoxia (decreased oxygen supply), maternal starvation (decreased glucose supply) and gestational hypertension (decreased uteroplacental blood circulation). Amino acids are used not only for fetal tissue synthesis but also meet the energy needs of the fetus. In third trimester, proteins are accreted at a rate of 1.5% of body weight per day.

Lipids are transferred to fetus as free fatty acids. Fetus does not use fatty acids for energy production and most of fat transferred to fetus is stored. Maximum fat storage occurs in later part of third trimester. Fat accounts for 15–20% of fetal weight at term gestation. Preterm birth and IUGR lead to decrease in subcutaneous and brown fat increasing the risk of temperature instability.

Most of fetal micronutrient accretion also occurs in the third trimester. Calcium is accreted at increasing rate as pregnancy advances to reach a peak accretion rate of 120–160 mg/kg/day in late third trimester. Calcium is transported against the concentration gradient to fetus and its level in fetus blood is regulated by parathyroid hormone (PTH). At birth when continuous supply of calcium is stopped from mother, there is surge in PTH levels to maintain the calcium levels in normal range. PTH surge may be impaired in conditions such as prematurity, maternal diabetes and birth asphyxia. In presence of these morbidities, a sick neonate on intravenous fluids may need parenteral calcium added to the fluids. Phosphorous is also transported against concentration gradient to fetus with peak accretion rate of 60–75 mg/kg/day in third trimester. Similarly, magnesium (3–5 mg/kg/day), copper (30 mg/kg/day), zinc (400 mg/kg/day) and iron (2–3 mg/kg/day) are also transferred and stored in fetus mainly in third trimester. Knowledge of rates of fetal accretion of nutrients is helpful in estimating nutritional needs of neonates born prematurely.

Thyroid hormones are essential for normal fetal growth. Maternal thyroid hormones do not play any significant role in fetal growth except in first trimester. Fetal thyroid starts functioning by about 12 weeks of gestation with appearance of thyroxine (T<sub>4</sub>), triiodothyronine (T<sub>3</sub>) and thyroid stimulating hormone (TSH) in fetal circulation. Levels of these hormones in fetus is higher than mother. Immediately after birth, there is surge in TSH levels in response to thermal stimulation of the newborn infant. In response to this T<sub>3</sub> and T<sub>4</sub> levels are increased in neonate and remain elevated for 2 weeks after birth.

## FETAL CIRCULATION AND GAS EXCHANGE

Fetus is dependent on placenta for gas exchange. Fetus receives oxygenated blood from the placenta through umbilical vein. Partial pressure of oxygen (PaO<sub>2</sub>) in umbilical venous blood is 20–40 mm Hg. More than half of this blood directly enters the inferior vena cava and rest passes through liver. In inferior vena cava, stream of blood coming from the umbilical vein and reaching the right atrium is preferentially directed through foramen ovale to the left atrium. This oxygenated blood is supplied mainly to coronary arteries, brain and upper part of the body. Less oxygenated blood coming from lower part of body in the inferior vena cava goes to the right ventricle. Pulmonary resistance is high because of lack of air in alveoli. Only 10% of right ventricular output goes to pulmonary circulation. Most of the output of the right ventricle is shunted through the ductus arteriosus to the aorta. This relatively deoxygenated blood supplies the lower part of the body and through two umbilical arteries to the placenta. Placenta is low resistance circulation and, therefore, receives largest amount (40%) of cardiac output.

Fetal tissue are able to maintain aerobic metabolism despite very low PaO<sub>2</sub> as compared to the extrauterine existence. Fetal hemoglobin (HbF) has higher oxygen binding capacity. For a given value of PaO<sub>2</sub>, HbF carries larger amount of oxygen as compared to adult hemoglobin. Higher heart rate and more red blood cell mass also ensure more oxygen delivery to the tissue each minute. Fetal oxygen demand is also lower due to lack of need of thermoregulation.

Alveoli in fetus are filled with lung fluid. This lung fluid is actively secreted by alveolar epithelium by chloride channels. Lung fluid moves up through the airways and is either swallowed or contributes to the volume of amniotic fluid. Ongoing production of lung fluid creates slight positive pressure in the alveoli and is necessary for normal lung growth. Pulmonary vasculature dilatation is dependent on presence of air in the alveoli. In absence of air, pulmonary vessels are constricted leading to high pulmonary vascular resistance.

**Table 2** Major milestones in the development of different organ systems

Time after fertilization	Cardiovascular system	Respiratory system	Gastrointestinal system	Urogenital system	Central nervous system
2 weeks	Primary heart field by heart progenitor cells				
3 weeks	Formation of heart tube		Primitive gut by folding of embryo Appearance of liver primordia	Appearance of primordial germ cells	Formation of neural plate
4 weeks	Cardiac looping	Formation of lung bud	Differentiation of esophagus Appearance of stomach Breakdown of oropharyngeal membrane	Appearance and disappearance of pronephros Appearance of mesonephros Division of cloaca starts	Neurulation
5 weeks	Beginning of formation of cardiac septa	Main stem bronchi		Appearance of metanephros	Prosencephalic and hemispheric formation
6 weeks	Arterial and venous morphogenesis	Pseudoglandular stage (Branching to form terminal bronchioles)	Gut rotation starts	Formation of urogenital ridge	Neuronal proliferation and migration
8 weeks	Formation of four-chambered heart		Breakdown of anal membrane	Disappearance of mesonephros	
10 weeks	Increase in size, maturation of different structures		Gut starts to return to abdominal cavity		
12 weeks					
16 weeks					
20 weeks					
24 weeks		Saccular stage (formation of primitive alveoli)	Increased length of small intestine		
28 weeks					
32 weeks					
36 weeks		Alveolar stage (Maturation of alveoli)		Completion of nephrogenesis	Myelination
Birth and postnatal period	Closure of foramen ovale and ductus arteriosus				

As process of parturition begins reabsorption of lung fluid starts by appearance of epithelial sodium channels in the alveolar cells. This transition from fluid secreting to fluid absorbing alveolar lining is facilitated by increase in levels of catecholamines and steroids in fetoplacental circulation with onset of labor. At birth, air enters the alveoli and pulmonary vasculature dilates leading to decrease in pulmonary vascular resistance. As umbilical cord is clamped, low resistance placental circulation is removed and systemic vascular resistance increases. This leads to functional closure of foramen ovale and change in direction of blood flow in ductus arteriosus. Perfusion of oxygen rich blood in ductus arteriosus from aorta causes constriction of the ductus leading to first functional and then anatomic closure.

## ASSESSMENT OF FETAL WELL-BEING

Intrauterine fetal death can occur in presence of maternal complications such as gestational hypertension, abruptio placenta, diabetes or intrauterine infections. Complications in intrapartum period such as cord prolapse, eclampsia, nonprogression of labor are also associated with increased risk of fetal death. Antenatal

fetal surveillance can be used to detect the effect of fetal hypoxia or ischemia on physiological variables of the fetus. If alteration in fetal physiological variables is detected, suitable intervention such as induction of labor or operative delivery can be chosen by the clinical care team.

## Fetal Heart Rate

This is commonly monitored alone or in combination with other biophysical variables. Fetal heart rate (FHR) normally shows acceleration, whenever, fetus has spontaneous body movements. In response to fetal hypoxia, this variability in fetal heart rate is decreased or lost. Nonstress test (NST) can be done to detect this normal FHR variability. NST is said to be reactive, if there are at least two accelerations that reach 15 beats/min above the baseline heart rate and each acceleration lasts for at least 15 seconds before returning to baseline. NST is said to be nonreactive, if two accelerations meeting these criteria do not occur within 40 min. A reactive NST is reassuring for fetal well-being. On the other hand, nonreactive NST can be false positive and may need further confirmation.

## Biophysical Profile (BPP)

This is another commonly used test to assess fetal well-being. It has five components including NST:

1. At least one episode of fetal breathing lasting at least 30 seconds.
2. At least three discrete body or limb movements.
3. At least one episode of active extension with return to flexion of a limb or trunk, or the opening and closing of a fetal hand.
4. Single vertical pocket of amniotic fluid measuring more than or equal to 2 cm.
5. Reactive NST.

A score of 2 is assigned to each parameter, if present and score of 0 is assigned, if absent. A total score of 8 or 10 indicates fetal well-being. Score of 6 is considered equivocal. Pregnancy can be terminated or test can be repeated in 24 hours depending on gestation. A score of 4 or less is abnormal and pregnancy needs to be terminated to decrease the risk of fetal death. Reactive NST or BPP score of 8–10 are reassuring and can be repeated after 1 week.

## Doppler Measurement of Blood Flow

Doppler blood flow measurements in umbilical artery can also be used to assess health of the fetus. With decreasing blood flow to the uteroplacental circulation blood flow during diastole in umbilical artery starts decreasing. Absence or reversal of blood flow during diastole in umbilical artery is commonly used to decide about delivery of a fetus affected by intrauterine growth restriction.

During labor also FHR is monitored to detect fetal distress. Normal baseline fetal heart rate is 110–160 beats/minute. A fetus suffering from intrapartum hypoxia can display loss of FHR variability, FHR deceleration or fetal tachycardia. FHR deceleration can be of three types: early, late and variable. Early decelerations coincide with peak of the uterine contraction and are caused by fetal head compression. These are usually associated with a favorable fetal outcome. Variable decelerations as the name implies vary in shape, depth, and duration. They usually coincide with uterine contraction and usually have a favorable outcome. Late decelerations start and return to baseline more gradually (> 30 seconds). They start and reach their nadir after the onset and

peak of uterine contractions. Recurrent late decelerations are non-reassuring and indicate need of delivery of the fetus.

### IN A NUTSHELL

1. Fetal growth is influenced by genetic potential, intrauterine environment, transplacental supply of nutrients and maternal exposure to environmental agents.
2. Teratogenic influence of environmental, infectious and metabolic agents can cause various birth defects during first two months of pregnancy (embryonic phase).
3. Most of fetal micronutrient accretion also occurs in the third trimester. Premature birth or uteroplacental placental insufficiency leads to deficiency of micronutrients such as iron, calcium, phosphorous and magnesium in fetus.
4. Fetal well-being can be monitored by observing physiological changes in fetal heart rate and nervous system functions such as fetal tone and movements.
5. Fetuses with intrauterine growth restriction are at significant risk of perinatal morbidity, mortality and long-term growth and metabolic complications.

## Chapter 11.2

# Maternal Influence on the Fetus

Jayashree Mondkar, Swati Manerkar

Fetal growth and development depends upon the maternal environment in utero, placental function and the inherent growth potential of the fetus. If all influences are conducive, fetal outcome is optimal. Adverse influences have far reaching consequences extending beyond fetal and neonatal period, right into adulthood.

## MATERNAL NUTRITION

The fetus gains 85% of its birth weight in the last half of pregnancy and depends upon maternal nutrient intake and on maternal endogenous substrate stores as precursors for fetal tissue synthesis. In utero growth of the fetus also requires an appropriate endocrine milieu. Insulin and insulin-like growth factors are the chief growth hormones in utero. Fetal insulin promotes the deposition of glycogen and adipose tissue. It also stimulates amino acid uptake and protein synthesis in muscle. Other fetal hormones, such as growth hormone, thyroid hormone and corticosteroids, have less well-defined effects on fetal growth.

Prepregnancy weight and pregnancy weight gain are two important independent variables that affect fetal growth. Mothers with low prepregnancy body mass index (BMI) less than 19.8, are more likely to deliver a baby with fetal growth restriction unless pregnancy weight gain is optimal.

The nutritional intake of the mother during pregnancy is also an important determinant of fetal weight gain. As fetal growth accelerates in the latter half of pregnancy, the requirement for nutrients increases. Substrate deficiency during this period has been shown to result in an overall reduction in birth weight. A reduction by 300–500 g in birth weight has been observed in acute famine states. Thus, maternal weight gain during pregnancy is a surrogate marker for fetal growth and weight gain. Poor weight gain by 16 weeks' gestation may predict low birth weight. Mothers with a normal BMI (19.8–26) may require a weight gain of 11.5–16 kg for optimal fetal outcomes. Underweight mothers may require a pregnancy weight gain of 12.5–18 kg to prevent fetal growth restriction. Nutritional supplementation during pregnancy has shown to improve fetal weight. Additional calories, rather than protein supplementation, have been shown to correlate best with enhanced fetal weight. An average intake of 1,500 kcal/day during pregnancy is recommended.

There is substantial evidence that micronutrient deficiency particularly maternal iron deficiency anemia increases the risk of preterm delivery and subsequent low birth weight. Multicomponent micronutrient supplementation has also been shown to enhance fetal growth in developing countries.

Other factors that influence maternal nutrition and thereby fetal growth include maternal age below 18 years, young unmarried mothers, short interpregnancy interval less than 2 years, chronic maternal illnesses, low socioeconomic status, heavy work during pregnancy.

## CHRONIC MATERNAL PROBLEMS

### Maternal Medical Problems

Maternal medical problems, like chronic hypertension, heart disease, pulmonary disorders, sickle cell anemia affects fetal and neonatal outcomes through uterine ischemia, hypoxemia or both resulting in intrauterine growth restriction (IUGR), perinatal asphyxia and their consequent morbidities.

### Hypertension

Hypertension is the most common medical problem in pregnancy, affecting 10–15% of all pregnant women. Uncontrolled hypertension whether chronic or gestational hypertension, has profound effects on the fetus and neonate and is a major cause of perinatal mortality and morbidity. Women with hypertensive disorders are at higher risk for preterm delivery and placental abruption, and their fetuses are at risk for IUGR due to the uteroplacental insufficiency, decidual ischemia and decidual thrombosis.

Mortality and morbidity in growth restricted, small for gestational age (SGA) infants are increased compared with those who are appropriate for gestational age. SGA infants at birth have many clinical problems that include perinatal asphyxia, meconium aspiration syndrome, pulmonary hypertension, impaired thermoregulation, hypoglycemia, polycythemia and hyperviscosity; SGA infants are at higher risk for impaired physical growth, neurodevelopment and difficulties with attention span. Cognitive performance is generally lower in SGA infants at the ages of 1–6 years compared with those who are appropriate for gestational age. Adults who were SGA infants could be at higher risk for ischemic heart diseases and essential hypertension.

### Diabetes

Uncontrolled maternal diabetes during pregnancy is associated with significant perinatal morbidity and mortality. Maternal hyperglycemia and the resultant fetal hyperinsulinemia are central to the pathophysiology of diabetic complications of pregnancy.

Uncontrolled periconceptional type I and type II diabetes are associated with a fourfold increase in the rate of congenital malformations compared to nondiabetic pregnancies. All organ systems including cardiac, central nervous system, genitourinary, musculoskeletal systems may be affected. Cardiac defects especially transposition of great vessels is the most common anomaly in infants of diabetic mothers. Sacral dysgenesis and caudal regression syndrome are also far commoner in babies of periconceptional diabetic mothers.

Glycemic control during embryogenesis is a critical factor in the genesis of diabetes-associated birth defects. Congenital malformation rate was noted to be nine-fold higher in the poorly controlled group ( $HbA_{1c} \geq 7.5$ ) than in the well-controlled group ( $HbA_{1c} < 7.5$ ). However, the risk of delivering a malformed infant in well-controlled periconceptional diabetics is equivalent to that in the general population.

Putative mechanisms causing malformations due to fetal hyperglycemia during embryogenesis include excessive formation of oxygen radicals in the mitochondria of susceptible tissues, leading to the formation of hydroperoxides, which inhibit prostacyclin. The resulting excessive production of thromboxanes and other prostaglandins may disrupt vascularization of developing tissues. Reduced levels of arachidonic acid and myoinositol and accumulation of sorbitol and trace metals in the embryo have also been implicated. Infants of gestational diabetic mothers are at the same risk for congenital anomalies as the nondiabetic population.

Fetuses of all types of uncontrolled diabetic mothers are at increased risk of the effects of fetal hyperglycemia and hyperinsulinism. Maternal hyperglycemia stimulates fetal hyperinsulinemia, which in turn accelerates fuel utilization and growth. The growth acceleration is more evident by 24 weeks. There is excessive adipose tissue deposition, visceral organ hypertrophy, and acceleration of body mass accretion causing macrosomia, often with birth weight greater than 4,000 g. Head growth remains normal despite marked degrees of hyperglycemia. The central deposition of fat is a key characteristic of diabetic macrosomia and causes problems associated with vaginal delivery in these pregnancies. Macrosomia is associated with the increased likelihood of operative delivery, shoulder dystocia, and brachial plexus injury.

The important neonatal morbidities include metabolic problems like hypoglycemia, hypocalcemia, respiratory distress, need for assisted ventilation, meconium aspiration, polycythemia, hyperbilirubinemia, etc. Some neonates of gestational diabetic mothers may present with hypertrophic cardiomyopathy with a thickened myocardium and significant septal hypertrophy.

### Thyroid Disturbances

For the first 10–12 weeks of pregnancy, the baby is completely dependent on the mother for the production of thyroid hormone. By the end of the first trimester, the baby's thyroid begins to produce thyroid hormone of its own. Transfer of thyroxine T4 during the first trimester from the mother to the fetus is of great importance because fetal brain development appears to depend on maternally derived T4. Maternal hypothyroidism during early gestation can lead to neurologic damage of the fetus even if the fetus is subsequently euthyroid. The baby, however also remains dependent on the mother for ingestion of adequate amounts of iodine, which is essential to make the thyroid hormones. Maternal hypothyroidism and hyperthyroidism can affect the baby.

### Hyperthyroidism

Eighty to eighty-five percent of maternal hyperthyroidism occurs due to Graves disease. Inadequately treated maternal hyperthyroidism can result in early labor and pre-eclampsia. Fetal effects include fetal tachycardia, fetal growth restriction, prematurity and stillbirths. Also the transplacental passage of thyrotropin (TSH) receptor stimulating antibodies can cause transient neonatal thyrotoxicosis. If the TSH receptor suppressing antibodies are excessive in a mother with earlier Graves disease, fetal hypothyroidism may occur. In the mother on antithyroid therapy, fetal hyperthyroidism is rare as antithyroid drugs also cross the placenta.

Antithyroid drug therapy with methimazole (MMI), propylthiouracil (PTU) is used for the treatment of hyperthyroidism. Both the drugs cross the placenta and can potentially affect the baby's thyroid function. MMI is best avoided in the first trimester due to possible association with aplasia cutis congenita, tracheoesophageal fistula and choanal atresia. Fetal hypothyroidism and goiter can occur even with doses in the therapeutic range for the mother. Beta-blockers can be used during pregnancy to help treat significant palpitations and tremor due to hyperthyroidism. Breastfeeding can continue as usual, and PTU is the drug of choice in lactating women as it is highly protein bound.

Thus, infants of mothers with Graves disease can present with hyper- or hypothyroidism. The baby will require periodic assessment of his/her thyroid function to ensure maintenance of normal thyroid status.

### Hypothyroidism

The common causes of maternal hypothyroidism are the autoimmune disorder, Hashimoto thyroiditis and iodine deficiency. Pregnant women who are under producing thyroxine are, therefore, at risk of having children with lower intelligence quotients and learning problems, such as attention-deficit hyperactivity disorder. The hypothyroid mother needs treatment with levothyroxine throughout pregnancy. Fetal effects include preterm birth, IUGR, congenital anomalies, goiter, fetal and perinatal death. Neurodevelopmental impairment may occur especially if both fetus and mother are hypothyroid. Women who are well-controlled during pregnancy have good pregnancy outcomes.

The newborn baby needs to be screened for hypothyroidism after birth and treatment with levothyroxine (10–15 µg/kg/day) needs to be started by 2 weeks of life if detected to be thyroid deficient so as to ensure normal brain development.

## Autoimmune Disorders

A number of maternal autoimmune and alloimmune disorders can cause fetal effects of varying severity due to transplacental transfer of antibodies.

### Maternal Idiopathic Thrombocytopenic Purpura

Thrombocytopenia of the fetus or newborn is caused by active transplacental transfer of the antiplatelet antibodies in about 10% of mothers with idiopathic thrombocytopenic purpura (ITP). A low platelet count increases the risk of hemorrhage; however intrauterine fetal hemorrhage is not common with ITP. Babies are at increased risk of cerebral hemorrhage due to birth trauma or bleeding subsequently in the neonatal period.

### Maternal Antinuclear Antibodies

Antinuclear antibodies are produced in various maternal immunological diseases. Antidouble-stranded DNA (anti-dsDNA) antibodies that are specific for systemic lupus erythematosus and anti-Ro and La antibodies can cross the placenta and cause neonatal lupus in 1% of infants. Infants present with cardiac, dermatologic, hepatic, and hematologic manifestations. The skin lesions on the face and scalp, often have a periorbital distribution and may be present at birth. Maternal anti-Ro and anti-La antibodies and complement components are deposited in fetal heart tissues, leading to inflammation, calcification, necrosis, and fibrosis of the conducting tissue leading to heart block that is often complete and irreversible and may be combined with cardiomyopathy. About 10% of fetuses with congenital heart block are born with hydrops fetalis and congestive heart failure.

### Maternal Antiphospholipid Antibodies

Maternal antiphospholipid antibodies promote clotting in arteries and veins (i.e., thrombophilia) by activation of endothelial cells, via oxidant-mediated injury to endothelium, and by modulating the regulatory function of coagulation proteins. Women with APLA have a high incidence of recurrent miscarriage (three or more consecutive losses of pregnancy). Other potential complications of pregnancy include preeclampsia, placental insufficiency, fetal growth impairment, preterm birth, maternal thrombosis (including stroke), and complications of treatment.

## Alloimmune Disorders

When small amounts of fetal blood enter the maternal circulation through breaks in the fetomaternal interface, these fetal blood cells are recognized as antigens by the maternal immunologic system and provoke an immune response. On a subsequent stimulus, the antibodies response being immunoglobulin G (IgG), cross into fetus causing cell destruction. The two important prototypes of alloimmune disorders are erythroblastosis fetalis and neonatal alloimmune thrombocytopenia.

Red cell alloimmunization occurs due to materno-fetal red cell antigen incompatibility, the commonest being RhD incompatibility. However, ABO, any of the minor group antigens, like C, E, Kell, etc., can also cause hemolytic disease in the newborn. Maternal antibodies caused by transplacental transfer of fetal cells and stimulation of the maternal immune system cross in to the fetal circulation and cause hemolysis of fetal red cells. The severity if the disease increases with subsequent sensitized pregnancies from mild to severe hyperbilirubinemia after birth to severe anemia and hydrops fetalis in utero.

The condition is preventable by administering to the mother anti-D immunoglobulins at 28 weeks and at term in the first and all subsequent conceptions when maternal antibody titers are negative. Monitoring maternal antibody titers during pregnancy is needed. Once titers are positive, close fetal surveillance by ultrasound and middle cerebral arterial Doppler is required.

Neonatal alloimmune (also known as isoimmune) thrombocytopenia (NAIT) has a pathogenesis similar to Rh disease. A mother with the human platelet antigen-1a (HPA-1a) negative platelets is sensitized by antigen-positive fetal platelets gaining access to the maternal circulation via breaches in the placental barrier. As a result, the mother produces antiplatelet antibodies that cross the placenta and destroy the fetal platelets. Fifty percent of NAIT cases manifest during the first pregnancy. This is believed to be due to higher immunogenicity of the platelet antigen and by the smaller size of the platelets, which facilitates their fetomaternal transfusion.

Most neonates are asymptomatic, and the thrombocytopenia is detected by a blood count performed for other perinatal causes. In some cases, neonates present with generalized petechiae, hemorrhage into abdominal viscera, excessive bleeding after venepuncture or circumcision, or, in extreme cases, abnormal neurologic manifestations secondary to intracranial hemorrhage. The platelet count commonly decreases further during the first week after birth. Antenatal intracranial bleeds in the fetus may occur.

## MATERNAL INFECTIONS

Pregnant women are exposed to infections in the community through all trimesters. Manifestations of infection in the mother may be most trivial hence remain unnoticed yet may have devastating effects on the fetus. Infection in the mother does not always mean the baby will be affected. For many infections, the risk to the baby varies when contracted at particular stage of pregnancy. When infection is transmitted vertically in utero the resulting fetal-neonatal infection is called a congenital infection. When infection is contracted during labor, it is described as a perinatally acquired infection.

The effects of congenitally acquired infection may be quite different from and more severe than the effects of the same infection acquired after birth especially when acquired in the period of organogenesis. The risk is highest when a primary infection occurs compared to a reinfection in the mother wherein protective antibodies are already present and protect the fetus to a large extent.

Infection of the embryo or fetus can result in death and resorption of the embryo, abortion, stillbirth or livebirth of a premature or term infant who may or may not be normal. The effects of in utero infection appear in the live-born infant as low birth weight, developmental anomalies, congenital disease or none of these. Infections acquired in utero may persist after birth and cause significant abnormalities soon after birth or may not be recognized for months or years.

The infant is protected from the microbial flora of the mother's genital tract by the maternal membranes. If delivery is delayed after membrane rupture, the vaginal microflora can ascend and in some cases produce inflammation of fetal membranes, umbilical cord, and placenta. Fetal infections can also occur from aspiration of infected amniotic fluid. Some viruses are present in the genital secretions [herpes simplex virus, cytomegalovirus, or human immunodeficiency virus (HIV)] or blood (hepatitis B virus or HIV). If delivery follows shortly after membrane rupture, the infant may be colonized during passage down the birth canal.

## MATERNAL DRUG EXPOSURE

In most situations, the risk of adverse fetal effects of medication taken by the mother is not known. Timing of exposure of the drugs is important. The most critical period for teratogenic effects of drugs is believed to be 15–60 days after conception. Drugs taken after organogenesis can affect growth and development of the fetus, in particular the developing brain. The FDA has categorized pregnancy risk of medications as A to D and category X. Category C and D medications put the fetus at increased risk of teratogenesis and category X drugs are contraindicated in pregnancy.

## LATE PREGNANCY AND LABOR

Though the antepartum period may pass off uneventfully problems in the late third trimester or labor may put the fetus at risk for perinatal asphyxia and adverse outcomes. Besides spectrum of pregnancy-associated hypertensive disorders, antepartum hemorrhage may cause prematurity, perinatal asphyxia or can also cause neonatal shock. Any problems that prolong the second stage of labor may also predispose the baby to perinatal asphyxia.

## Adverse Intrauterine Environment:

### Long-term Outcomes

There is sufficient evidence to demonstrate association between small size at birth and the risk of chronic adult diseases, such as coronary artery disease, hypertension, stroke, type 2 diabetes mellitus, and osteoporosis. This hypothesis was first put forth by David Barker and is called the *Barker hypothesis*. Malnutrition during gestation that includes macronutrients or micronutrients causes intrauterine adaptation of the fetus for survival despite adversity by conserving energy supply at the expense of growth, ensuring a reduced fetal demand, resulting in the birth of a small baby. These adaptations generate a *thrifty phenotype* which persists after birth. With the availability of nutrients after birth, catch-up growth occurs which tends to increase deposition of white adipose tissue resulting in adiposity, particularly visceral adiposity; a rearrangement of skeletal muscle mitochondria; and increased oxidative injury. These changes set the stage for metabolic syndrome, diabetes mellitus, and coronary artery disease in adulthood.

### IN A NUTSHELL

1. Prepregnancy weight and pregnancy weight gain are two important independent variables that affect fetal growth.
2. Micronutrient deficiency particularly maternal iron deficiency anemia increases the risk of preterm delivery and subsequent low birth weight.
3. Chronic hypertension, heart disease, pulmonary disorders, diabetes and anemia in the mother cause uterine ischemia or hypoxia; and may result in IUGR, perinatal asphyxia and their consequent morbidities.
4. Infection of the embryo or fetus acquired from mother can result in abortion, stillbirth, prematurity, IUGR, developmental anomalies, congenital disease. Infections acquired in utero may persist after birth and cause significant abnormalities soon after birth or may not be recognized for months or years.
5. The most critical period for teratogenic effects of drugs taken by the mother is believed to be 15–60 days after conception.

## Chapter 11.3

# Transition of the Fetus to Newborn

Siddarth Ramji

Fetal life and physiology are very different from what is expected of it once it delivers as a neonate and has to exist in the extrauterine environment. The fetus for its existence derives its nutrition, and oxygenation, via the placenta, which also serves as an organ of excretion for the fetus. The fetus is thermally insulated and immunologically protected. However, the process of birth requires the fetus to navigate the transition to its neonatal life by making adaptations in its respiratory, cardiovascular, gastrointestinal and renal systems, and has also to make major metabolic adjustments. Understanding these physiological changes is key to the management of disorders in the newborn resulting from the transitional maladaptation. This chapter will focus the physiologic adaptations that take place in the newborn during this transition from intrauterine to extrauterine life.

## PULMONARY AND RESPIRATORY CHANGES

The first prerequisite is that the lungs must begin to function as an organ of gas exchange. This requires the establishment of pulmonary ventilation through expansion of lungs after birth and establishment of pulmonary circulation. For pulmonary ventilation to be established, it is important that the fetal lung be cleared of its fluid to receive air with onset of breathing after birth, and establishment of adequate respiratory efforts after birth.

### Clearance of Lung Fluid

Fetal lung is essentially secretory, and presence of fluid in fetal lungs is critical to its development. At birth since the neonate needs to start breathing, this fluid has to be cleared rapidly. The switch from secretion to absorption in the distal epithelium of the lung at birth is facilitated by the interaction of epinephrine, glucocorticoids, thyroid hormones and oxygen. The clearance of lung fluid at birth is triggered by the onset of labor, which results in a sudden increase in fetal catecholamines. They in turn, acting via the  $\beta$ -adrenoceptors on the type II alveolar cells, promote active sodium absorption due to increased  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase activity. The  $\beta$ -adrenoceptor mediated sodium reabsorption is primed by T3 and glucocorticoids, which in turn operate by upregulating the maturation of this absorptive process by the expression of amiloride-sensitive sodium channel [epithelial sodium channel (ENaC)]. The rise in alveolar partial pressure of oxygen ( $\text{PaO}_2$ ) with the first breath is in part responsible for the activation of the  $\text{Na}^+$  pump, which is activated by the binding of the oxygen responsive nuclear factor kappa-light-chain-enhancer of activated B-cells (NF- $\kappa\text{B}$ ) to  $\alpha$ -ENaC promoter. The expression of ENaC appears to be delayed in infants born by cesarean section which partly explains the delayed clearance of lung fluid in such infants and increased risk of transient tachypnea in these newborns. Since ENaC expression is increased in late gestation, it also explains the higher risk of delayed fluid clearance in very preterm neonates.

### Initiation of Breathing

Cessation of placental gas exchange results in transient hypoxia which triggers the medullary respiratory center. It is also believed that the decrease in environmental temperature, and tactile, visual and auditory stimuli have a role in initiating breathing efforts after birth.

The first few breaths, especially crying against a closed glottis, increase end expiratory pressure allowing air to remain at the end of expiration in the alveoli, resulting in the establishment of a functional residual volume (FRC). The adequacy of surfactant in the alveoli facilitates the persistent of FRC by lowering surface tension. The net result is an increase in the alveolar  $\text{PaO}_2$  which facilitates reabsorption of lung fluid, as described above, into the pulmonary circulation. Increased alveolar oxygen also results in decreased pulmonary resistance and enhanced pulmonary and lymphatic flow.

## FETAL TO NEONATAL CIRCULATION

### Fetal Circulation

The fetal circulation is a *parallel circuit* characterized by low systemic resistance and high pulmonary resistance, with shunts at the level of ductus venosus, ductus arteriosus (DA) and foramen ovale (FO). The gas exchange takes place in the intervillous spaces of the placenta with  $\text{PO}_2$  in the umbilical artery being 15–25 mm Hg, and in the umbilical vein, it being 30–35 mm Hg. Almost two-third of the blood from the umbilical vein (receiving blood from the placenta) bypasses the liver via the ductus venosus to enter the inferior vena cava (IVC) and then the right atrium. Almost 50% of this oxygenated blood from the umbilical vein is preferentially shunted across the FO into the left atrium and ventricle and perfuses the head, neck and upper trunk. The remainder of the blood from the IVC mixes with the blood from the superior vena cava ( $\text{PO}_2$  12–14 mm Hg) and enters the right ventricle and the pulmonary artery. Since the pulmonary vascular resistance is high and systemic resistance is low (placental circulation being a low-pressure circuit) most of this blood (with lower oxygenation) is shunted into the descending aorta via the DA to perfuse the lower part of the body (Fig. 1).

### Neonatal Circulation

In contrast, the extrauterine circulation is one in *series* with no shunts (Fig. 2). The pulmonary vascular resistance is lower than the systemic resistance. The gas exchange occurs in the lungs at the alveolar-capillary interface with an arterial  $\text{PO}_2$  of more than 60 mm Hg.

### Cardiovascular Adaptation at Birth

Two significant events enable this adaptation to take place: (1) decrease in pulmonary vascular tone, and (2) increase in systemic vascular resistance due to loss of placental circulation.

#### Decrease in Vascular Resistance

The initiation of respiration and the consequent expansion of alveoli decrease the alveolar hydrostatic pressure on the pulmonary capillaries contributing to decrease in the pulmonary vascular resistance. The increase in venous oxygen pressure consequent to onset of breathing appears to influence the decrease in pulmonary vascular tone. This is probably mediated by arachidonic acid metabolites such as prostaglandins, thromboxane and leukotrienes. Evidence suggests that these agents probably trigger another substance endothelial derived relaxing factor which is identical to nitric oxide, which may be the final common pathway through which vasodilatation is achieved.

#### Loss of Placental Circulation

The loss of placental circulation at birth by cutting of the cord, results in increase in systemic pressure. The consequent increase in descending aortic pressure decreases the right to left shunting at the level of DA. Simultaneously, the increase in pulmonary flow decreases the pressure in the right atrium and increases the pressure in the left atrium resulting in closure of the FO, and decrease in the right to left shunting at the atrial level.

**Figure 1** Fetal circulation

Abbreviations: DA, ductus arteriosus; IVC, inferior vena cava; SVC, superior vena cava.

**Figure 2** Neonatal circulation

Abbreviations: DA, ductus arteriosus; IVC, inferior vena cava; SVC, superior vena cava.

### Ductal Closure

Ductal closure occurs in two stages. In healthy term neonates, functional closure begins at birth and is complete by 96 hours. The functional closure of the DA is probably mediated by the increase in muscle tone due to increased oxygen levels in blood and decrease in levels of prostaglandins that dilate the vessels. This functional closure is followed by anatomic closure due to endothelial proliferation and fibrosis.

However, this phase of transition is vulnerable to reversal to the fetal circulatory stage with reversal of shunts due to hypoxia, acidosis and infection resulting in the state of *persistent pulmonary hypertension of the newborn*.

### THERMAL REGULATION AND METABOLIC ADAPTATION

The fetus in utero was largely protected from the factors influencing thermal losses such as evaporation, radiation, convection and conduction. Even though the newborn can generate heat by nonthermal thermogenesis, in a sick and tiny neonate this mechanism may become ineffective especially in the presence of hypoxia and nutritional deprivation.

The fetus receives a steady supply of glucose from the placenta at a rate of 4–6 mg/kg/min. In the latter half of gestation, almost half of the glucose supplied to the fetus is stored in the fetus as glycogen. However, when the cord is cut, it results in a fall in blood glucose levels during the first 2 hours after birth. This fall in glucose together with the increase in catecholamines due to the stress of birthing process stimulates enzymes such as hepatic phosphorylase which induces glycogenolysis to facilitate supply of glucose to the newborn infant. Hepatic glycogenolysis and gluconeogenesis is the only source of fuel for the newborn after birth till feeding is established. Glucose oxidation contributes to about 70% of the energy needs of the brain. The neonatal brain is able to use alternate fuel sources for bridging this gap by utilizing mainly ketones and to a far lesser extent lactate. The key adaptation at birth is the glucagon surge with its low insulin/glucagon ratio that results in glucagon mobilization. Similarly, changes also take place in amino acid and lipid metabolism.

### Adaptation in Preterm

In contrast to the commonly held belief, preterm neonates do not have lower levels of plasma glucose than term infants. This is probably due to the more aggressive feeding policies practiced in neonatal units at present. However, they are unable to mount an appropriate ketogenic response to decreasing blood glucose levels. The low ketone levels are probably due to a combination of impaired lipolysis and ketogenesis. Unlike term neonates, no change is noted in the gut hormones after the first enteral feed, but after repeated bolus feeding surges in gut hormones are seen by the end of the first week.

### Adaptation in Growth-retarded Neonates

Failure of metabolic adaptation is more frequently seen in growth-retarded neonates than those who have grown appropriately. The possible reasons for this include depletion of glycogen reserves, decreased phosphoenolpyruvate carboxylase activity, limited mobilization and subsequent oxidation of fatty acids and relative functional hyperinsulinism. Their gluconeogenic capacities are also lower as evidenced by increased levels of gluconeogenic precursors such as lactate and alanine. Feeding of human milk appears to promote normal adaptation in this group of infants.

## FEEDING ADAPTATION

There is very little demand on the fetal digestive tract. However, after birth, the baby has to feed using its digestive tract and therefore compelled to make rapid adaptive changes. The gastrointestinal tract has to undergo rapid maturation. The infant has to be able to suck and also coordinate its sucking, and swallowing with its breathing. The maturation of this coordinated process is complex and matures slowly in preterm. This often is the reason why even late preterm infants also stay a longer time in hospital. The intestinal peristalsis has to mature rapidly to eliminate the meconium (composition: water about 80%, intestinal secretions, dead mucosal cells, bile and pancreatic juices, mucus, lanugo and vernix) and be able to accommodate the milk fed to the newborn.

## RENAL ADAPTATION AND FLUID BALANCE

Placenta is the primary organ for excretion, fluid and electrolyte balance in the fetus. But after birth, the kidney has to adapt to take over these functions. To be able to maintain fluid and electrolyte homeostasis, there is a rapid increase in renal blood flow after birth and over the first 2 weeks glomerular filtration also increases by two-fold. Most aspects of renal function are immature at birth and these are more obvious in the preterm neonate. The maximum concentrating ability of the neonatal kidney is less than that of the adult and are also less capable of handling water load. Immature tubular functions often result in increased water and electrolyte losses which have to be compensated especially in the preterm infant. Extrauterine life also imposes increased risk of insensible water losses (particularly at birth) which predispose especially the preterm neonates, to hypothermia, dehydration and risks of hyponatremia. The immature glomerular functions also predispose neonates to bicarbonate loss and acidosis.

## HEMATOLOGIC CHANGES

The predominant hemoglobin in the fetus is fetal hemoglobin which is characterized by its high affinity for oxygen. This is due to its decreased binding to 2,3-glycerophosphate compared to adult

hemoglobin. Production of adult hemoglobin in fetal life starts in late gestation while the production of fetal hemoglobin is switched off at birth. The newborn has a high hemoglobin at birth (average of 17 g/dL), which falls by 8–12 weeks to its nadir of about 10 g/dL.

## CIRCADIAN RHYTHM

The fetal circadian rhythms are established as early as 20 weeks of gestation. The regulatory mechanism for the fetal diurnal rhythm is unclear. After birth it takes about 3 months for the sleep and wakefulness circadian rhythm to be established.

### IN A NUTSHELL

1. The most significant transition at birth is from placental dependent gas exchange to lung dependent gas exchange. This is facilitated by fetal lung fluid clearing in late gestation and with onset of labor.
2. Circulatory adaptation results in a shift from a *parallel* fetal circulation to a circulation in *series* with closure of shunts at the levels of ductus arteriosus and foramen ovale and increased pulmonary flow facilitated by decrease in pulmonary vasculature resistance.
3. Metabolic adaptation involves gluconeogenic and glycogenolytic mechanism to maintain euglycemia soon after birth till adequate feeding is established. These are impaired in preterm and growth retarded infants which predispose them to increased risk of hypoglycemia.
4. Feeding of breastmilk facilitates postnatal gut adaptation.

## Chapter 11.4

# Neonatal Mortality and Morbidities: An Overview

Aparna Chandrasekaran, M Jeeva Sankar

The neonatal period, the first 28 days of life, carries the highest risk of mortality per day than any other period during the entire childhood. The daily risk of mortality in the first 4 weeks of life is about 30-fold higher than the period from 1 month to 59 months of age. Indeed, of every two children who die before reaching 5 years of age, one dies in the first 28 days of life. Still, newborn health did not receive the attention it deserves until a few years ago. This resulted in a slow decline in neonatal mortality rate (NMR) in most countries which hampered their chances of achieving the Millennium Development Goal-4 (MDG 4) by year 2015. The fact that neonatal deaths are largely unaffected by *traditional* child health interventions like immunization, oral rehydration therapy, oral antibiotics for pneumonia, etc., has rightly turned the spotlight on those interventions that are known to reduce the neonatal mortality. This has led to significant gains in the last 4–5 years but a lot needs to be done to compensate for the early years of inertia.

This chapter provides an overview of the burden, trends, and causes of neonatal mortality, and the burden of common morbidities at both global and country level. **Box 1** enlists the common terminologies related to perinatal and neonatal mortality along with their definitions.

## NEONATAL MORTALITY: BURDEN, TRENDS, AND GOALS

### Global

Around 2.9 million newborns die every year across the globe (2012 estimates). The number has declined from 4.4 million in 1990 to 2.9 million in 2012, a reduction by nearly 35% which is lower than the decline of about 50% in postneonatal child mortality during the same period. The current global NMR is 21 per 1000 livebirths, the rate varying from 1 per 1000 livebirths (Japan) to 49.5 per 1000 livebirths (Sierra Leone). The MDG 4 targeted a reduction in under-5 deaths by two-thirds by year 2015 from the baseline of 1990. While some countries are on track to achieve this goal, many countries are not. Looking beyond 2015, the countries have now committed themselves to *Every Newborn* target of fewer than 12 per 1000 livebirths and 10 per 1000 livebirths by 2030 and 2035, respectively.

### India

About 0.78 million neonates die every year in India, the highest for any country in the world. Indeed, India alone contributes to more than a quarter of global neonatal deaths. The total number of deaths has declined from 1.32 million in 1990 which translates into a reduction of about 42%. In contrast, the postneonatal child deaths declined by more than 50% during the same period. The disproportionately slow decline in neonatal mortality has led to an increasing proportion of child deaths occurring in the neonatal period—from 46% in 1990 to 57% in 2012.

The current (2014) NMR of India is 28 per 1000 livebirths, much higher than the global average. Given the current infant mortality and under-five mortality rates of 40 and 49 per 1000 livebirths respectively, about 70% of infant deaths and more than half of under-five child deaths in the country occur during the neonatal period (**Fig. 1**). The NMR in 2012 varied from 7 per 1000 livebirths in Kerala to 39 per 1000 livebirths in Madhya Pradesh and Odisha

### BOX 1 Common terminologies and their definitions

- **Neonatal death:** The death of a live born infant during the period that commences at birth and ends 28 completed days after birth
- **Neonatal mortality rate (NMR):** Number of deaths among all livebirths during the first 28 days of life expressed per 1000 livebirths
- **Early neonatal mortality rate (ENMR):** Number of neonatal deaths less than 7 days of life expressed per 1000 livebirths
- **Late neonatal mortality rate (LNMR):** Number of neonatal deaths between 7 days and 28 days of life expressed per 1000 livebirths
- **Infant mortality rate:** Probability of dying between birth and one year of age expressed per 1000 livebirths
- **Under-5 child mortality rate:** Probability of dying between birth and five years of age expressed per 1000 livebirths
- **Stillbirth:** The death of a fetus weighing at least 500 g (or if birth weight unavailable, after 22 completed weeks of gestation or crown heel length of 25 cm or more) before the complete expulsion from its mother
- **Perinatal mortality rate:** Number of deaths of fetuses weighing at least 500 g (or if birth weight unavailable, after 22 completed weeks of gestation or crown heel length of 25 cm or more) plus the number of early neonatal deaths per 1000 total births.

**Figure 1** Neonatal deaths as a percentage of infant and under-5 deaths in India

Source: SRS Statistical Report, 2012.

(**Fig. 2**). The early neonatal mortality rate (ENMR), deaths in the first week of life, is 22 per 1000 livebirths, while late NMR is 6 per 1000 livebirths. The first week of life alone accounts for 45% of total under-5 child deaths. Unfortunately, the rate of decline in early NMR is much lower than that of late NMR (**Fig. 3**).

The projected NMR of India for year 2035, assuming the same rate of reduction in NMR from 1990 to 2012, is 16 per 1000 livebirths, much higher than the *Every Newborn* target of fewer than 10 per 1000 livebirths. This underlines the need to implement and scale-up simple and effective interventions on an urgent basis across different settings.

## WHERE DO NEWBORNS DIE?

### Global

Most of the neonatal deaths (about 99%) occur in low- and middle-income countries. Only five countries, India, Nigeria, Pakistan, China, and Democratic Republic of Congo, account for more than half of these deaths.

### India

Four states, Uttar Pradesh, Madhya Pradesh, Bihar, and Rajasthan, alone contribute to about 55% of total neonatal deaths in India (**Fig. 4**). Together, these four states account for about 15% of *global* neonatal deaths. The proportion of neonatal deaths occurring in the health facility ranges from 5% in Jharkhand to more than 80%

**Figure 2** Neonatal mortality rate (NMR) of India and larger Indian states  
Source: SRS Statistical Report, 2012.

**Figure 3** Trends of neonatal mortality rate (NMR), early neonatal mortality rate (ENMR) and late neonatal mortality rate (LNMR) in India  
Source: SRS Statistical Reports (2000-2012).

in Kerala. More than half of neonatal deaths occur at home in all states except those with least NMR and high rates of institutional births namely, Kerala, Tamil Nadu, and Delhi. The NMR in rural areas is twice that of urban areas—33 versus 16 per 1000 livebirths. The discrepancy is more marked (i.e., a difference of 60% or more) in Andhra Pradesh, Assam, Jharkhand, and Kerala.

## WHY DO NEWBORNS DIE?

### Global

A systematic analysis of causes of neonatal and childhood deaths identified complications from preterm birth (35%), infections

(sepsis/meningitis/pneumonia/tetanus/diarrhea; 27%), and intrapartum-related conditions (birth asphyxia; 23%) to be the three major causes of neonatal deaths across the globe.

### India

The same three conditions, preterm birth complications, infections, and intrapartum-related conditions/birth asphyxia, cause majority of deaths in India as well. But as compared to global figures, a higher proportion of infection-related deaths occur in India (**Fig. 5**). In addition to the direct causes, a host of other socioeconomic, demographic, and other factors play an indirect role in causing neonatal deaths. The NMR among the poorest 20%

**Figure 4** Burden of neonatal deaths in Indian states

Note: 'Rest' includes smaller states like Uttarakhand, Goa, and all union territories

(AP–Andhra Pradesh; As–Assam; Chh–Chhattisgarh; Del–Delhi; Guj–Gujarat; Har–Haryana; HP–Himachal Pradesh; Jh–Jharkhand; JK–Jammu and Kashmir; KI–Kerala; Kn–Karnataka; Mah–Maharashtra; MP–Madhya Pradesh; Odi–Odisha; Pb–Punjab; Raj–Rajasthan; TN–Tamil Nadu; UP–Uttar Pradesh; WB–West Bengal)

of the population is more than double the NMR of the richest 20%. Girls do have a lower *biological* risk of mortality during infancy but a higher *social* risk of neonatal and infant mortality due to sub-optimal nutrition and reluctance of parents to seek early and optimal healthcare. Other social factors like early maternal age at childbirth and less than optimal birth spacing also contribute to the high mortality and morbidities.

## WHEN DO NEWBORNS DIE?

### Global

Of the total deaths that occur during the neonatal period, about 75% occur in the first week of life. The first three days of life alone account for more than half of the total neonatal deaths.

### India

The timing of overall and cause-specific neonatal deaths in India is not different from the global figures. About three-fourths of the total neonatal deaths occur in the first week of life, the first day alone accounting for more than one-third of the deaths (**Figs 6A and B**). Almost all asphyxia related deaths and majority of prematurity related deaths (83%) happen within the first week of life but more than half of infection related deaths occur after the first week.

## PERINATAL MORTALITY AND STILLBIRTH RATE

The perinatal mortality rate (PMR) is defined as the number of stillbirths and infant deaths of less than 7 days per 1000 total births (livebirths and stillbirths) during the year while stillbirth rate (SBR) is defined as the number of stillbirths per 1000 total births during the year.

**Figure 5** Causes of neonatal deaths in India

The current perinatal mortality rate of India (2013) has been estimated to be 28 per 1000 births. It ranges from 17 per 1000 births in urban areas to 31 per 1000 births in rural areas. As with NMR, the perinatal mortality rate is not uniform across the country; the PMR of Kerala is only 9 per 1000 births whereas that of Odisha is 35 per 1000 births.

The SBR of India for the year 2013 is estimated at 4 per 1000 births. The figures of both SBR and PMR are likely to be underestimates, as stillbirths are extremely difficult to capture. Also, there is a great room for misclassification of these deaths. Interestingly, the SBR for year 2009, as estimated by the international agencies, was 22.1 per 1000 births while the SRS estimate for year 2010 was only 7 per 1000 births.

## NEONATAL MORBIDITIES

While mortality is just the proverbial tip of iceberg, the morbidities constitute the huge base that remains hidden and often does not receive the due attention it deserves. **Box 2** provides definitions for the common neonatal morbidities.

### Global

The profile of neonatal morbidities is likely to be different across the globe because of the differences in demographic and social characteristics, ethnicity, economic status, and more importantly, the availability and quality of intrapartum and postnatal care. A large network study involving one hospital each in six countries of South East Asia Region (SEAR) identified low birth weight (LBW) (< 2500 g; 19.0%), prematurity (13.1%), birth asphyxia (8.7%), neonatal jaundice (6.4%), and sepsis (5.7%) to be the most common morbidities among livebirths at these tertiary care hospitals.

### India

The common morbidities reported in a large multicenter study involving 18 major hospitals across India include LBW, preterm births, birth asphyxia, neonatal jaundice, and sepsis among others (**Table 1**). The figures might be an overestimate of the true incidence in the population, as many of the study hospitals cater to high-risk pregnancies. A community-based study from Gadchiroli, Maharashtra involving 763 neonates found LBW, breastfeeding problems, neonatal infections, umbilical sepsis, and hypothermia to be the common morbidities (**Table 2**). Only 12.8% neonates did not suffer from any of the morbidities. The major neonatal morbidities are described in detail in the subsequent sections. A brief summary of the burden of the most common and severe morbidities is provided here.

### Low Birth Weight/Preterm Birth

Globally, a total of 18 million babies are born every year with a LBW, i.e., less than 2500 g. About 60% of them are born at term after fetal growth restriction while the rest are due to prematurity. Around 14 million neonates were born preterm, i.e., before 37 weeks of gestation, every year in the world.

**Figures 6A and B** Timing of neonatal deaths in India. (A) Distribution of neonatal deaths (week-wise); (B) Proportion of neonates dying in the first week of life

Source: Sankar MJ 2015 (Systematic review-under publication).

#### BOX 2 Definition of common neonatal morbidities

**Low birth weight (LBW):** Birth weight less than 2500 g

**Preterm:** Gestational age of less than 37 completed weeks (i.e. less than 259 days)

**Respiratory distress:** Presence of at least 2 of the following criteria: respiratory rate > 60/min, Subcostal/intercostal recessions and expiratory grunt/groaning

**Neonatal sepsis (Culture positive):** Presence of clinical picture suggestive of septicemia, pneumonia or meningitis along with the isolation of pathogens from blood or CSF or urine or pathological evidence of sepsis on autopsy

**Neonatal sepsis (Culture negative):** In a neonate having clinical picture suggestive of septicemia, the presence of any one of the following criteria is sufficient for assigning probable diagnosis of sepsis:

- Maternal risk factors: maternal fever or foul smelling liquor or prolonged rupture of membranes (> 24 hours)
- Positive septic screen (two of the five parameters namely, TLC (< 5000/cmm, band to total polymorph ratio of > 0.2, absolute neutrophil count less than 1800/cmm, C-reactive protein > 1 mg/dL and micro ESR > 15 mm in 1st hour)
- Radiological evidences of pneumonia

**Birth asphyxia:** Apgar score of less than 7 at 1 min of age

**Hypothermia:** Skin temperature below 36.5°C

**Hypoglycemia:** Whole blood glucose of less than 40 mg/dL

**Umbilical sepsis:** Presence of redness or swelling, with or without pus, in the skin surrounding the umbilical cord stump

**Hyperbilirubinemia:** Serum bilirubin greater than 15 mg/dL in a term neonate or < 15 mg/dL in a preterm neonate, and requiring treatment in the form of phototherapy or exchange transfusion

**Major congenital malformation:** A malformation that is life threatening or requires surgical correction.

In India, about 30% of all livebirths, 7.5 million, are born with a LBW. This accounts for 42% of the global burden, the largest for any country. The relative proportion of term growth restricted infants and preterm infants are almost the same as the global figure. Around 3.5 million neonates are born preterm every year in the country. This constitutes a quarter of the total preterm births.

Low birth weight/preterm infants are at higher risk of dying in the neonatal period and beyond, when compared to term normal birth weight (NBW) babies. Community-based studies indicate that the LBW infants are at 11–13 times increased risk of dying than NBW infants. Indeed, more than 80% of total neonatal deaths occur among LBW/preterm neonates. These infants are also at a higher risk of asphyxia, sepsis, hypothermia, and feeding problems. LBW increases the odds of underweight, stunting, and wasting in the first 5 years of life; about 28% of underweight and stunting, and 22% of wasting at 6 months of age can be attributed to LBW. Preterm/LBW infants are also at high risk of major neurodevelopmental disabilities. Around 10% of LBW infants have major disabilities at 3 years of corrected age. The mean IQ of LBW infants at six years, though within normal limits, are significantly lower than that of NBW infants. LBW infants are also predisposed to a variety of adult onset diseases in later life because of the anomalous programming of affected fetuses.

**Table 1** Incidence of selected morbidities in babies born in health facilities of India

Morbidity	Incidence (%) (N = 145,623)
Low birth weight (LBW)	31.3
Preterm	14.5
Birth asphyxia	8.4
Neonatal jaundice	3.3
Sepsis	3.0
Hypoxic ischemic encephalopathy (HIE)	1.4
Respiratory distress syndrome (RDS)	1.2
Seizures	1.0
Hypoglycemia	0.9
Cardiac malformations	0.5

**Table 2** Incidence of selected morbidities in community settings in India

Morbidity	Incidence (%) (N = 763)
Low birth weight	41.9
Breastfeeding problems	25.6
Umbilical sepsis	19.8
Neonatal sepsis/pneumonia	18.0
Hypothermia	17.0
Skin infections	12.4
Conjunctivitis	12.3
Prematurity	9.8
Birth asphyxia	6.2
Diarrhea	5.5
Abnormal jaundice	1.7
Hemorrhage	1.4
Congenital malformations	1.3

## Neonatal Sepsis

Neonatal sepsis encompasses various systemic infections of the newborn such as septicemia, meningitis, pneumonia, arthritis, osteomyelitis, and urinary tract infections. Studies from developing countries report an incidence ranging from 30 to 170 per 1000 livebirths, whereas those from the developed countries report rates of only 1 to 3 per 1000 livebirths. The burden of neonatal sepsis is huge in India. Hospital based studies suggest an incidence of 30 per 1000 livebirths, while community-based studies indicate an incidence of 2.7–17%. Sepsis is the most common morbidity in neonates referred to a hospital from home/another health facility; up to 60% of these neonates are labeled as having neonatal sepsis during their hospital stay. Nearly one-fifth of neonates with sepsis die in the hospital; the figure rises to up to 50% for those with culture proven sepsis. They stay longer in the hospital, consume more resources, and are also at a high-risk of major neurodevelopmental disabilities at a later age.

## Birth Asphyxia

Intrapartum related conditions or birth asphyxia not only results in neonatal deaths but also accounts for a significant proportion of stillbirths. It is difficult to estimate the true burden of asphyxia because of the different definitions used in studies from different countries. Community-based studies from India report an incidence of 2–16.2%, with the reported case fatality rates ranging from 38.5% to 74%. The incidence of moderate and severe asphyxia was 2.8% and 5.6%, respectively in a large multicenter study involving 18 major hospitals across India; the case fatality rate was relatively low at about 8.7%.

## REDUCING THE BURDEN OF NEONATAL MORTALITY AND MORBIDITY

### Global

Newborn health has received an unprecedented attention by researchers, policymakers, and governments and global funding agencies in the last few years. This has helped in identifying the effective interventions that are likely to reduce the neonatal mortality, preparing roadmaps for their implementation/scale-up in low-and middle-income country settings, and mobilizing finances and other support to facilitate the entire process. The most critical interventions thus identified are enlisted in **Figure 7**. These interventions span across the antenatal, labor and delivery, and postnatal periods, which underscores the importance of *continuum of care* from the adolescent period of the prospective mother to the childhood period of her progeny.

It has been estimated that increased coverage and quality of the listed interventions can avert 71% of the neonatal deaths and 33% of stillbirths by year 2025. Most of this effect is attributable to those interventions that are delivered at health facilities. Among these interventions, the ones with the maximum benefit are those that are delivered during labor and childbirth, followed by those related to care of small and sick newborns. Institutional births and facility-based care of sick neonates therefore assume a critical role in reducing the burden of neonatal mortality and morbidities.

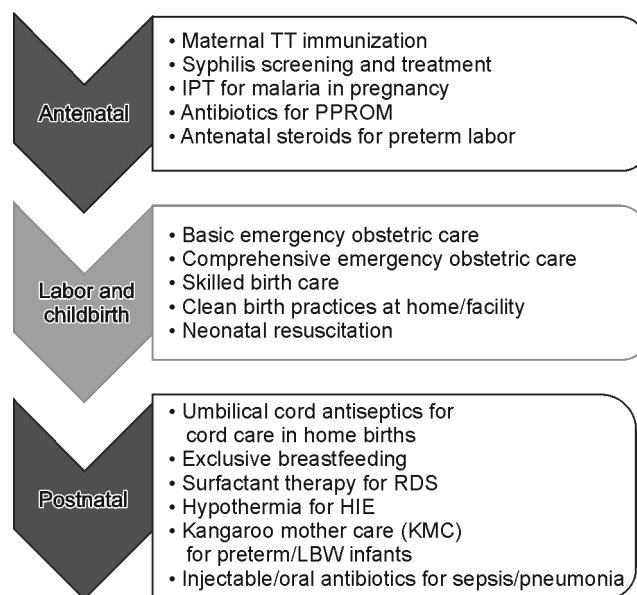

Many developing countries have taken sincere efforts to improve the rates of institutional births in the last decade. For example, India introduced a conditional cash transfer scheme, *Janani Suraksha Yojana (JSY)*, in mid-2005 to promote births in the health facilities, following which there has been a huge surge in the rates of institutional births. But this quantum increase has not readily translated into a major reduction in the neonatal or perinatal

mortality rates. The primary reason for this discrepancy is the sub-optimal quality of care at birth and during the postnatal period in the health facilities. The situation is almost similar in most developing countries. The key is therefore to improve the quality of care in the health facilities. Recent estimates indicate that addressing the quality gap for institutional births alone would prevent 1.3 million neonatal deaths and 0.5 million stillbirths globally every year.

## India

India has witnessed a significant improvement in neonatal health after the introduction of National Rural Health Mission (NRHM) in mid-2005. Apart from the JSY, the country has launched several new initiatives under NRHM to improve the neonatal care. The Facility-based Newborn Care aims to build a three-tier system of neonatal care encompassing the Primary Health Centers, the Community Health Centers, and the District Hospitals. The Home-based Newborn Care program allows home visiting by the Accredited Social Health Activists (ASHAs) for neonatal examination, sickness detection, and family counseling. The *Janani Shishu Suraksha Karyakram (JSSK)* entitles mothers and infants to free transportation, care, medicines, diagnostics, and blood products in all public facilities. The recently launched *Rashtriya Bal Suraksha Karyakram (RBSK)* focuses on screening infants for selected birth defects and developmental delays. The newly created Special Newborn Care Units (SNCUs) in the district hospitals across the nation cater to more than 0.6 million newborn babies each year.

Notwithstanding this newfound focus on neonatal health, the annual rate of reduction in NMR and ENMR still lags behind IMR and U5MR. India is likely to miss the MDG-4, if effective interventions known to reduce NMR and in particular, ENMR, are not implemented and/or scaled up in the next 2–3 years. The country has to increase the coverage of key interventions and also improve the quality of care in health facilities on an urgent basis.

**Figure 7** Interventions to reduce neonatal mortality  
 Abbreviations: TT, tetanus toxoid; IPT, Intermittent preventive treatment; PPRM, preterm prelabor rupture of membranes; RDS, respiratory distress syndrome; HIE, hypoxic ischemic encephalopathy; KMC, Kangaroo mother care.

## IN A NUTSHELL

1. Around 2.9 million newborns die every year across the globe; India contributes to one-fourth of the global burden of newborn deaths.
2. In India, about 0.78 million neonates die every year—the highest for any country in the world.
3. About 70% of infant deaths and more than half of under-five child deaths in India occur during the neonatal period.
4. Globally, 99% of newborn deaths occur in developing nations. In India, four states—Uttar Pradesh, Madhya Pradesh, Bihar, and Rajasthan—alone contribute to about 55% of total neonatal deaths.
5. The major causes of neonatal deaths are prematurity (35%), infections (27%) and intrapartum-related conditions (birth asphyxia; 23%); the profile is not different in India, except for the fact that the proportion of deaths due to infections is higher than the global average.
6. Of the total deaths that happen during the neonatal period, three-fourths occur in the first week of life, and one half within the first 3 days.
7. Almost all asphyxia-related deaths and majority of prematurity related deaths (83%) happen within the first week of life but more than half of infection related deaths occur after the first week.
8. The perinatal mortality and stillbirth rates of India are 28 per 1000 births and 7 per 1000 births, respectively; these are, however, likely to be underestimates of the true burden of perinatal deaths and stillbirths.
9. The most common neonatal morbidities include low birth weight (LBW), preterm births, birth asphyxia, sepsis, and neonatal jaundice.
10. Implementation of select evidence-based interventions during antenatal, labor and child birth, and postnatal periods can avert 71% of neonatal deaths and one-third of the still births across the globe by 2025.

## Chapter 11.5

# Organization of Neonatal Care

Subhash Chandra Shaw, Vinod K Paul

Neonatal health is the key to child survival. Organized newborn care that started in India in the early sixties at a few teaching hospitals has taken a center stage in the country's national child health programs ever since the Child Survival and Safe Motherhood program was launched in 1992 when essential newborn care was introduced. Neonatal health strategies are linked closely to maternal care including antenatal care, institutional deliveries, emergency obstetric care (EmOC) and postnatal care.

There are two broad domains of neonatal care in the public health system in India: the home-based newborn care (HBNC) and the facility-based newborn care (FBNC). In addition, neonatal care is provided in large government hospitals (in medical colleges, maternity hospitals) and the private sector hospitals. HBNC is provided by Accredited Social Health Activists, who are the frontline community health workers. They pay seven visits to mothers and newborns (on days 1, 3, 7, 14, 21, 28 and 42 of birth) for home births, and six visits to the facility-born babies (no visit on day 1). The babies are weighed and examined for sickness. Mothers are counseled on newborn care and postpartum care. Sick neonates are referred. FBNC is extremely important in reducing neonatal mortality. The next sections will dwell in detail on care of neonates in facilities, mainly in public health sector.

## LEVELS OF CARE

It is a system of tiered perinatal and neonatal care, based on the capacity and capability of their hospitals and physicians to handle the degree of complexity of the patients referred to them. The broad objectives of this categorization are to achieve quality of care to all newborns, maximum utilization of resources, and reasonable cost-effectiveness.

## American Academy of Pediatrics Classification

The updated classification of American Academy of Pediatrics consists of basic care (level I), specialty care (level II) and subspecialty care (level III, level IV; **Table 1**). The neonatal unit should be located near maternity areas, in particular, the delivery rooms. For practical purposes, for 2,000 deliveries, an 8–10 bedded nursery is required. The general physical norms of level II onwards units include: space of 10 m<sup>2</sup> for each baby, 24 × 7 water supply with enough wash basins, electricity backup, thermal-controlled environment that maintains temperature at 26–28°C and 12 air changes per hour, 8–12 electrical outlets per baby bassinet/incubator, at least 100 foot candle light intensity, and sound level not exceeding 75 decibels. The main newborn care area should be complemented by mothers' room, waiting area, nurse and doctor duty rooms, utilities room, pharmacy, area for total parenteral nutrition, stores, etc. For level III/IV nursery, the ratio of nurse to bed will be 1:1 or higher. For level II unit, it may be 1:2. In recent time, a developmentally conducive environment in the nurseries is promoted. This has comfortable day-night pattern, toys for individual babies and gentle music.

The neonatal units are technology intense. Incubators, radiant warmers, weighing scales, phototherapy units, infusion pumps, monitoring devices, continuous positive airway pressure machines, ventilators, etc., are integral part of neonatal units. The norms for these are provided in various accreditation systems including those of the National Neonatology Forum. In addition, neonatal units must have impeccable infection control norms and systems.

## Facility-based Newborn Care

As per Indian public health standards, newborn care facilities are provided at three levels, i.e., maternal and child health (MCH) level I, MCH level II and MCH level III (**Table 2**).

*Newborn care corner* is a space within any delivery room (labor room or operation theatre) in any health facility where immediate care is provided to all newborns at birth. This area is mandatory for any health-care facility conducting deliveries.

**Table 1** Levels of neonatal care (American Academy of Pediatrics)

Level of care	Capabilities	Provider types
Level I Well newborn nursery	Neonatal resuscitation at every delivery, postnatal care to stable term newborn infants, stabilize and care for infants born between 35 weeks and 37 weeks gestation who remain physiologically stable, stabilize ill and those born at < 35 weeks gestation until transfer to a higher level of care	Pediatricians, family physicians, nurse practitioners
Level II Special care nursery	<i>Level I capabilities plus:</i> Care for infants born ≥ 32 weeks of gestation and weighing ≥ 1,500 g, provide care for infants convalescing after intensive care, provide mechanical ventilation for brief duration (< 24 hours) or continuous positive airway pressure or both, stabilize infants born before 32 weeks of gestation and weighing < 1,500 g until transfer to a neonatal intensive care facility	<i>Level I health providers plus:</i> Pediatric hospitals, neonatologists and neonatal nurse practitioners
Level III Neonatal intensive care unit	<i>Level II capabilities plus:</i> Provide sustained life support, provide comprehensive care for infants born < 32 weeks gestation and weighing < 1,500 g and infants born at all gestational ages and birth weight with critical illness, ready availability to full range of pediatric medical subspecialists, pediatric surgical specialists, pediatric anesthesiologists and pediatric ophthalmologists, full range of respiratory support including conventional and/or high-frequency ventilation and inhaled nitric oxide, perform advanced imaging with interpretation on an urgent basis, including CT, MRI and echocardiography	<i>Level II health providers plus:</i> Pediatric hospitals, neonatologists and neonatal nurse practitioners
Level IV Regional neonatal intensive care unit	<i>Level III capabilities plus:</i> Capability to provide surgical repair of complex congenital or acquired conditions, facilitate transport and provide outreach education, full range of medical and surgical subspecialists at the site	<i>Level III healthcare providers plus:</i> Pediatric surgical subspecialists

**Table 2** Levels of care of neonatal care facilities under the National Rural Health Mission, India

Health facility	All newborns at birth	Sick newborns
MCH Level I Primary health center (PHC)/subcenter (SC)	Newborn care corner in labor room	Prompt referral
MCH Level II Community health center (CHC)/first referral unit (FRU)	Newborn care corner in labor room and in operation theater	Newborn stabilization unit
MCH Level III District hospital	Newborn care corner in labor room and in operation theater	Special care newborn unit (SCNU)

Abbreviation: MCH, maternal and child health.

*Newborn stabilization unit* is situated within or in close proximity of a maternity ward where sick babies and low birth weight (LBW) infants greater than and equal to 1,800 g can be cared for during short periods. All community health centers/first referral units (CHCs/FRUs) need to have a neonatal stabilization unit, in addition to the newborn care corner.

*Special Care Newborn Unit (SCNU)* on the other hand is a neonatal unit which can provide special care (all care except assisted ventilation and major surgery) for sick newborns and LBW infants less than 1,800 g. All facilities with more than 3,000 deliveries (most district hospital and some subdistrict hospitals) per year should have SCNU.

Expected services to be provided at all newborn care facilities, as planned by Ministry of Health and Family Welfare, Government of India, are care at birth of all newborns (prevention of infection, provision of warmth, resuscitation, early initiation of breastfeeding and weighing of newborn), care of normal newborn (breastfeeding/feeding support) and immunization services. However, the level of care of sick newborn differs as mentioned in **Table 3**.

## SETTING UP OF NEWBORN CARE FACILITIES

- *Newborn care corner* An area about 20–30 square feet in size within labor rooms or operation theatre is required for setting up a newborn care corner and should be equipped with a radiant warmer, weighing scale, foot operated pump suction, syringe hub cutter and resuscitation kit.
- *Newborn stabilization unit* Comprises of at least four beds with a total of at least 200 square feet (50 square feet/bed) area with two beds in postnatal ward dedicated for rooming in. There should be 24 hours uninterrupted power and water supply. It should have high-intensity phototherapy units, laryngoscope set and electronic baby weighing scale.
- *Special care newborn unit* Recommended number of beds is 12 for 3,000 deliveries per year. Four beds are to be added for each 1,000 additional deliveries. On an average, a total area of 100 square feet per patient (50 square feet for patient care area and 50 square feet for ancillary area) is required. The ancillary area includes separate areas for hand washing and gowning area, nurses work station, clean area for mixing fluids and medications, doctors duty room, mother's area for breastmilk expression, unit store and a side lab. The number of rooming in beds required is 30% of SCNU beds. Each SCNU should have oxygen supply system with oxygen concentrators, pulse oximeters, electronic sphygmomanometer, multichannel monitor, electrocardiogram unit, mobile X-ray machine, transport incubator and electrical autoclave machine. The

needs of human resources as followed by Ministry of Health and Family Welfare, Government of India, are shown in **Table 4**.

More than 70% of newborns are normal and need minimal care and another 10% need supervised care at home. Supervised care at CHC and level II hospitals comprise about 16–18% of all newborns and level III is needed by 2–3% of all newborns. In a population of 1000,000, there will be 20,000–25,000 child births per year. There will be 1,800 neonates (8%) requiring hospital care, i.e., 60 beds for sick, premature and LBW neonates. There will be a need of five SCNU of 12 beds each per district. At least 60% of these beds should ideally be in government hospitals and rest in private setup.

Neonatal care must be linked to EmOC. EmOC includes services aimed at improving the availability, accessibility, quality and use of services for the treatment of complications that arise during pregnancy. Good quality EmOC should be universally available and accessible and all women should deliver their infants in the presence of a skilled birth attendant and these should be integrated into the health system.

At MCH level I, there should be a facility for basic EmOC. Basic EmOC includes administering antenatal steroids, administering parenteral antibiotics, administering uterotonic drugs (i.e., parenteral oxytocin), administering parenteral anticonvulsants for

**Table 3** Services at different levels of neonatal care under National Rural Health Mission, India

Duration of training	2 days	11 days for those who have not been trained in IMNCI and 5 days for those who are already trained in IMNCI	4 days training followed by 2 weeks of observership

Abbreviation: IMNCI, integrated management of neonatal and childhood illness.

pre-eclampsia and eclampsia (i.e., magnesium sulfate), manual removal of the placenta, removing retained products of conception (e.g., manual vacuum extraction, dilation and curettage), performing assisted vaginal delivery (e.g., vacuum extraction, forceps delivery), performing basic neonatal resuscitation. At MCH level II, there should be provision of cesarean section and blood transfusion in addition.

### Accreditation Guidelines for Levels of Care in India

National Neonatology Forum of India has published recently, the accreditation guidelines for neonatal units in the country. The classification of newborn units as level IA, level IB, level IH (subcenter or equivalent), level IIA, level IIB, level IIIA and level IIIB are based on criteria that include patient-care load, number of deliveries or capability of caring for neonates of a certain gestational age or birth weight, etc. (Table 5).

### ORGANIZING KANGAROO MOTHER CARE

Kangaroo Mother Care (KMC) is an evidence-based intervention for stable preterm/LBW infants. KMC is initiated in stable preterm/LBW neonates in the facilities and continued at home after discharge. Unstable or sick preterm/LBW neonates are cared for in the SCNUs. For such babies, their mothers provide breastmilk/feeding and other care. In addition, KMC is initiated under supervision of the nurses/doctors in the SCNUs by their mothers when babies become stable. With further improvement, babies are transferred out from the SCNU to the mother in the postnatal care where KMC is continued till discharge.

It is evident that mothers have an overwhelming role in the care of preterm/LBW neonates, in particular, for optimum KMC. It is therefore essential that each hospital that has an SCNU ensures that there is a provision of beds for the mother-baby dyads to facilitate KMC and other care. Accordingly, it is recommended that each hospital with a NICU or a nursery or an SCNU should have a KMC unit.

A KMC unit of eight beds would be required for a typical 20 bedded neonatal unit or SCNU and should be built as an extended part of the new/upcoming SCNUs. For the existing SCNUs, it should be located as close to the SCNU as possible in the existing/new premises. Air temperature should be maintained at 24–26°C with relative humidity of 50–60%. It should be well-lighted and well-ventilated and for each eight-bedded room a total of 1,500 square feet space is needed.

There should be adult hospital beds with railings (eight in number) with comfortable semireclining chairs next to each infant bed for mothers to impart KMC (eight in number). There should be provision of a resuscitation kit, oxygen cylinder and hood, clinical thermometers, a weighing machine, a refrigerator to keep breastmilk and drugs and a room thermometer.

### TRANSPORT SYSTEM

As a consequence of development of different levels of neonatal care, there has been an increased emphasis on in utero transfer of at risk mothers to the next higher center as shown in studies from Canada and New Zealand where the outcome of very LBW babies was found to be better in inborn rather than outborn babies. Many a time when the transfer of mother is not feasible, there should be a system in place to transport after birth from lower to higher level unit. Neonatal transport brings the intensive care environment to critically ill infants before and during inter and intrahospital transports. In India, neonatal transport is mostly self-transport by parents or done by the source hospital by utilizing private ambulances and semi-trained or ill-trained personnel. When the staff is less experienced, the risk of adverse events on such transports can be greater than with well-equipped and trained staff. Whereas organized transport services provide almost the same level of monitoring and the quality of care during the transport that is available in the advanced care facility. Ideally, it should have the ability to provide mechanical ventilation, multiple fluid infusion therapy and cardiorespiratory monitoring along with provision

**Table 5** National Neonatal Forum (NNF) levels of neonatal care for India

Levels of care	Gestational age and birth weight	Patient load (No. of admission in a year)	Comments
IA			NCC at PHC
IB	≥ 1,500 g, ≥ 32 weeks	≥ 100	NSU at CHC, FRU
IH			Government subcenter or equivalent
IIA	≥ 1,000 g, ≥ 30 weeks	≥ 200	Availability of CPAP Services of trained pediatrician in neonatology
IIB	≥ 1,000 g, ≥ 30 weeks	≥ 300	In addition, short-term basic ventilation
IIIA	Includes below 1,200 g		<i>Desirable elements in addition:</i> Prolonged conventional ventilation ROP screening High-risk follow-up services Metabolic screening Broad specialty course in pediatrics or short fellowship in neonatology
IIIB	Includes below 1,200 g		<i>In addition:</i> Advanced ventilation therapy including surfactant High-frequency ventilation In-house CT/MRI Neonatal surgical interventions DM/DNB program in neonatology

**Abbreviations:** NCC, newborn care corner; NSU, newborn stabilization unit; SCNU, special care newborn unit; PHC, primary health center; CHC, community health centers; FRU, first referral units; CPAP, continuous positive airway pressure; ROP, retinopathy of prematurity.

**Table 6** Description of neonatal transport system

Components	Comprised of	Comments
Human resources	Physician trained in neonatology Physician/nurse managing equipment, ambulance, personnel, communication and documentation Other skilled transport team members	All team members should be able to provide basic care to sick neonates: Keeping them warm during transport Asepsis Monitoring vitals Skilled in essential procedures like establishing venous access Providing positive pressure ventilation
Vehicle and equipment	Vehicle	Source of oxygen Power supply Sufficient light Secure fixation of incubator, monitors, infusion pumps Minimization of shaking, draught of air
	Equipment	Thermal support equipment ideally a transport incubator, if not then thermocol box, plastic wrap, insulating blankets or while doing Kangaroo mother care with mother Respiratory support equipment Suction and monitoring equipment Parenteral infusion equipment, medications
Communication and family support		Information about the newborn's clinical condition and prognosis Opportunity to ask and have questions answered by the team Information about the anticipated time frame of the transport and about the receiving hospital If the mother is accompanying the baby, then addressing her medical needs during transfer and after reaching referral hospital
Documentation and consent form		Patient demographic details (name, age, sex, gestational age and weight, place and name of referring hospital) Reason for transfer Detailed perinatal history, labor and delivery, neonatal resuscitation Current patient status, therapy and laboratory data Potential for deterioration and need for advance therapy like mechanical ventilation and exchange transfusion or diagnostic evaluation Referral note with provisional diagnosis and treatment given so far Consent form from parents
Feedback to referring unit	Verbal or written communication to the members of referring team	Details of medical illness, likely diagnosis, prognosis and likely duration of stay Reverse transport once stable

of maintenance of temperature. Till recently no functional model of either emergency response systems or assured transport for pregnant women or their babies existed in India. The components of an organized neonatal transport system are shown in **Table 6**.

### IN A NUTSHELL

1. Newborn care is classified into different levels of care to optimize neonatal outcome, for using the available resources effectively.
2. India has developed country-specific norms for neonatal care.
3. Neonatal care is closely linked to the levels of EmOC available in the health system.
4. An important component of organized neonatal care is a good medical transportation system.

# Section 12 NORMAL NEWBORN

**Section Editor** Siddarth Ramji

## Chapter 12.1

### Delivery Room Care of the Newborn

Siddarth Ramji

There are about 26 million births each year in India (which is almost one-fifth of the global burden) and of these, almost 0.8 million infants die before the age of 1 month (2012 data). India's share of neonatal deaths is almost one-third of the global neonatal deaths. Most common reasons for these deaths include causes related to asphyxia, infection and prematurity/low birthweight. Most of these neonatal deaths are preventable.

#### Why Care at Birth is Important?

Almost a third of all neonatal deaths in India occur within the first day of life. A baby's survival soon after delivery and thereafter is totally dependent on the caregivers and the mother. It is, therefore, important to provide the right care at birth to reduce the risk of mortality in the newborn infant.

#### IMMEDIATE NEWBORN CARE AT BIRTH

Every newborn infant, irrespective of his or her place of birth, gestation and birthweight, requires care that is essential for their survival. The components of *Essential Newborn Care* are summarized in **Box 1**. Over 90% of newborns would require all the steps of essential newborn care except resuscitation.

1. Deliver baby onto mother's abdomen/a dry warm surface next to mother
2. Dry the baby and wrap in warm dry towel
3. Assess breathing; if not breathing/gasping, initiate resuscitative steps
4. Cut the cord after 1–2 min of birth
5. Place baby on skin-to-skin contact with mother and initiate breastfeeding
6. Give vitamin K to all newborns
7. Weigh all newborns at birth.

#### BOX 1 Components of essential newborn care

- Delivering baby onto mother's abdomen
- Drying the baby and wrapping in warm dry towel
- Assessing newborn breathing; to initiate resuscitation if not breathing or is gasping
- Delay cord clamping to about 1–2 min after birth (except in babies needing resuscitation)
- Placing the baby on skin-to-skin contact with mother and initiating breastfeeding
- Giving vitamin K to all newborns
- Weighing all newborns at birth.

*Provision of warmth* The newborn infant at birth should be received in dry, warm and clean linen/towels and placed on the mother's abdomen without cutting the cord (**Fig. 1**). If it is not possible, the infant may be placed next to the mother on a warm surface. The baby should be immediately dried, including the scalp, and the wet linen discarded (**Fig. 2**). The infant should be rewrapped in fresh, dry and warm clean linen/towel.

The room where the baby delivers should be maintained at around 28°C. During delivery and soon after the baby's birth, it must be ensured that there are no fans running or windows open, which can result in heat loss through convective currents.

*Checking for breathing* If the baby is crying vigorously, the baby needs no other resuscitative care. *Routine suction of oral cavity must*

**Figure 1** Placing baby on mother's abdomen immediately after birth

**Figure 2** Drying the baby at birth

**Figure 3** Baby in skin-to-skin contact with mother in delivery room

be avoided in vigorous babies as it may result in vagal stimulation and apnea and/or bradycardia.

If the baby is not breathing or has gasping breathing efforts, it must be immediately separated from the mother by cutting the cord, placed under a radiant warmer and appropriate resuscitation steps initiated to establish adequate breathing in the newborn.

**Initiating skin-to-skin care and breastfeeding** After the cord is cut (about 1–3 min of birth), the baby should be placed prone between the mother's breast in skin-to-skin contact position (**Fig. 3**) and delivery room staff must assist mother to secure the baby. Wrap baby and mother with another prewarmed dry sheet.

It is vitally important for the mother and her infant that breastfeeding should be initiated within an hour after birth. The delivery room staff should ensure that breastfeeding is initiated as soon after delivery as possible. The advantages to the mother are that it aids in uterine involution (induced by release of oxytocin secondary to the suckling reflex), thus decreasing the risk of postpartum hemorrhage. The benefit to the baby is increased maternal-infant bonding, provision of nutrition and immunity (from colostrum). The baby can be supported by the delivery room staff so that it can suck on the mother's breast while in skin-to-skin contact in the prone position. Even mothers who deliver by cesarean section or assisted delivery should be supported for early breastfeeding and should not be separated from their newborns.

**Cord, skin and eye care** The umbilical cord should be cut with sterile scissors/blade about 2.5 cm from the abdominal skin surface. There is no evidence that use of local antiseptics prevent subsequent umbilical infection. The cord is best left dry without any application.

The infant should be cleaned to remove blood, mucus or meconium from its surface. Take care *not to remove* the vernix as it protects the newborn's skin from injury. Bathing the baby soon after birth is not recommended. Bathing should be postponed to a later date till the baby's temperature remains warm and stable.

The baby's eyes can be cleaned at birth with sterile cotton soaked in sterile water or normal saline. Each eye should be cleaned using a separate swab. Routine use of local antiseptic drops for prophylaxis is not recommended.

**Prevention of infection** To prevent infection at the time of birth, the principles of the 5 Cleans are universally adopted. It includes:

- Clean surface for delivery of mother and baby
- Clean hands (wash hands well with soap and water and preferably use gloves while conducting a delivery)
- Clean and sterile blade for cutting the cord

- Use a clean cord tie
- Umbilical cord to be kept clean and dry

**Vitamin K and immunizations** All newborn infants should be given 1 mg of intramuscular vitamin K soon after birth. This helps to prevent hemorrhagic disease of the newborn.

Depending on the local immunization policy, newborns should be administered the appropriate immunization in the delivery room such as the hepatitis vaccine or the oral polio vaccine.

**Risk identification** An important task of the attending physician in the delivery room is identifying newborn infants at high risk of morbidity or mortality. Such newborns need to be provided special care.

- **Birth asphyxia** Infants who do not establish spontaneous breathing by 5 min after birth would all need referral to a special care unit to manage postasphyxial problems such as convulsions, hypoglycemia, shock, renal failure, respiratory problems, etc. Even some neonates in need of assisted ventilation for more than 2 min may need observation in neonatal special care units for the first 24 hours.
- **Congenital malformations** Infants may have minor or major malformations. Those malformations which increase the risk of morbidity or mortality would need transfer to neonatal intensive care unit (NICU) or referral. Some of these that can be detected in the delivery room include meningomyelocele, hydrocephalus, large omphalocele, esophageal atresia, anal atresia and diaphragmatic hernia.
- **Low birthweight** Every baby must be weighed at birth. Newborns with birthweight less than 2,500 g (low birthweight) are at increased risk of illness. However, it is newborn infants who are less than 2,000 g who generally need to be assessed more carefully and most of infants less than 1,800 g may need care in special care neonatal units.
- **Preterm newborns** Preterm newborns (< 37 weeks gestation) need special care because many of them are at risk of feeding problems, hypothermia and infection.
- **Respiratory distress** Newborns with respiratory rates greater than 60 breaths/min, those with chest retractions or grunting would all need referral to a special care neonatal unit so that they can get appropriate respiratory support.

**Assessment before transfer out of delivery room** All babies should be assessed for stability before they are transferred out of the delivery room. A newborn should be shifted out with the mother if stable as per the following criteria:

- Normal temperature (36.5–37.4°C)
- No oozing from cord
- No respiratory distress
- Pink color
- Vigorous

**Flow chart 1** provides an algorithm for care of baby in the delivery room.

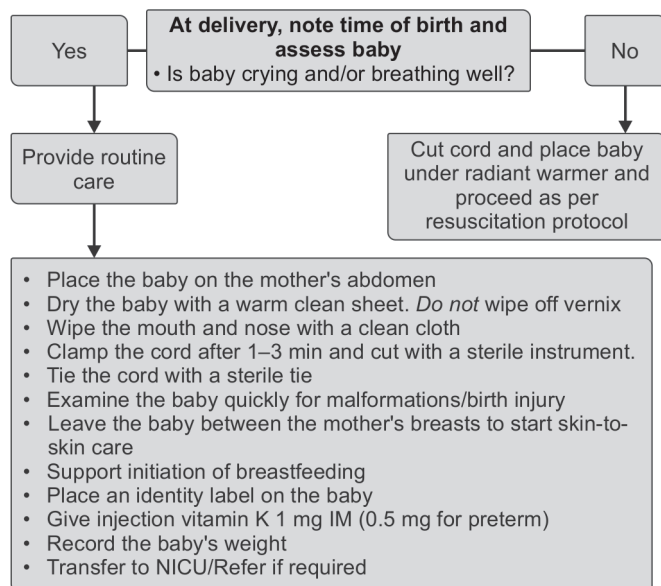

## NEWBORN CARE CORNER

It is essential that every delivery room has a newborn care corner. This is a space within the delivery room for facilitating immediate care of the newborn, especially for those who need resuscitation or those at-risk babies who are awaiting referral or transfer to a special care newborn unit. **Box 2** provides a list of equipment and supplies that should be available in the corner.

## NEONATAL RESUSCITATION

Approximately 10% of newborns require some assistance to begin breathing at birth; about 1% needs extensive resuscitative measures to survive. The ABCs of resuscitation are the same for babies as for

**Flow chart 1** An algorithm for providing care at birth to a newborn infant

Abbreviations: IM, intramuscular; NICU, neonatal intensive care unit.

#### BOX 2 Essential equipment and supplies for a newborn care corner

- **Equipment:**
  - Radiant warmer with bassinet
  - Suction equipment
  - Weighing machine
  - Self-inflating resuscitation bag (500 mL) with masks (size 0, 1)
  - Oxygen source
  - Laryngoscope (straight blade, size 0, 1)
  - Wall clock
  - Room thermometer
- **Supplies:**
  - Clean baby sheets
  - Sterile cord ties
  - Sterile gloves
  - Sterile blade/scissors
  - Mucus extractors
  - Suction catheters (10F, 12F)
  - Feeding tube (6F, 8F)
  - Endotracheal tubes (3 mm, 3.5 mm)
  - IV cannula (24G)
  - Drugs (Injection epinephrine, normal saline, injection vitamin K).

adults. Ensure that the *Airway* is open and clear. Be sure that there is *breathing*, whether spontaneous or assisted. Make certain that there is adequate *circulation* of oxygenated blood. Newly born babies are wet following birth and heat loss is great. Therefore, it is also important to maintain body temperature during resuscitation.

#### Determining if a Baby Needs Resuscitation

The need for resuscitation in a baby is determined by looking at the breathing of the baby. Babies who are vigorously crying or have good visible regular chest movements do not need any resuscitation. Babies who are apneic or gasping (deep, single irregular inspiratory efforts) need resuscitative assistance. **Flow chart 2** provides the neonatal resuscitation guidelines adapted for India from the International Liaison Committee on Resuscitation (ILCOR) 2010 guidelines.

**Figure 4** Positioning of the baby with shoulder roll in place

#### Initial Steps of Resuscitation

Once the decision for resuscitation has been taken, the initial steps should be initiated immediately. The components of initial steps include the following:

- Drying
- Positioning
- Clearing airway
- Provision of tactile stimulus

The baby should be placed under a radiant warmer, dried if already not done earlier. The baby must be positioned with neck slightly extended by placing a shoulder roll (**Fig. 4**). The airway would need to be cleared with a mucus extractor and if the infant is still not breathing, then tactile stimulus by flicking the soles or rubbing the back may be carried out to initiate breathing.

**Meconium-stained amniotic fluid** Suction should not be done routinely in vigorous babies even if there is meconium-stained amniotic fluid. In nonvigorous babies who are born through meconium-stained amniotic fluid, oral suction should be followed by tracheal suction (to clear the upper airway of meconium) before provision of tactile stimulus.

#### Assessment of Baby

The baby's breathing and heart rate should be assessed after provision of initial steps. If the baby has good breathing efforts and the heart rate is more than 100 beats/min (assessed by auscultation of heart beats and counting for 6 sec and multiplying by 10 to get beats per minute), continue providing routine essential care as described in **Flow chart 1**.

- **Baby has poor breathing efforts/is apneic or has a heart rate less than 100 beats/min** One must initiate positive pressure ventilation (PPV) with bag and mask. One must also consider connecting a pulse oximeter to the right wrist of the baby to assess oxygenation as cyanosis in the baby at birth is a poor indicator of the adequacy of oxygenation.
- **Adequate breathing efforts, heart rate greater than 100 beats/min and has respiratory distress** Connect a pulse oximeter to the right wrist of the baby to assess oxygenation and provide supplementary oxygen titrated to the target oxygen saturations for the age of the baby as shown in **Box 3**, by using an oxygen blender and adjusting the inspired oxygen concentration ( $\text{FiO}_2$ ). If the newborn is a preterm infant, and facilities are available, then CPAP may be initiated in the delivery room before transfer to NICU.

#### Positive Pressure Ventilation

Positive pressure ventilation is initiated if one of the following indications exists:

```
graph TD
    Start([Note the time  
Receive baby in dry, warm linen]) --> Q1{Is baby breathing/crying?}
    Q1 -- No --> Box1[• Cut cord immediately and place under radiant warmer  
• Provide initial steps (dry, position, clear airway, tactile stimulus)]
    Q1 -- Yes --> Q2{Gasping, apnea or HR < 100 bpm?}
    Box1 --> Q2
    Q2 -- No --> Q3{Labored breathing or persistent cyanosis?}
    Q2 -- Yes --> Box2[Initiate PPV using room air]
    Box2 --> Q4{Heart rate after 5 inflations: < 100 bpm?}
    Q4 -- No --> Box3[Baby breathing well and heart rate > 100 bpm]
    Q4 -- Yes --> Box5[Look for Chest Rise; if not  
• Ensure open airway  
• Reduce leaks  
• Consider increasing pressure]
    Box3 --> Q5{PPV < 1 min}
    Box5 --> Q5
    Q5 -- Yes --> Box6[Observational care with mother]
    Q5 -- No --> Box7[Postresuscitation care in NICU]
    Box7 --> Box8[If heart rate < 60 bpm and chest rising  
• Continue PPV, add 100% oxygen, consider intubation  
• Start chest compressions 3 compression to 1 breath]
    Box8 --> Box9[Consider:  
• Hypovolemia  
• Pneumothorax]
    Box9 --> Box8
    Box8 --> Box10[Baby breathing well and heart rate > 100 bpm]
    Box10 --> Box7
    Box11[If heart rate not detectable or < 60 bpm  
Administer epinephrine (1:10000), 0.1–0.3 mL/kg IV; If endotracheal route give 0.5–1.0 mL/kg] --> Box8
```

### BOX 3 Target oxygen saturations in the first 10 min after birth

*Acceptable productual SpO<sub>2</sub>*

1 min:	60–65%
2 min:	65–70%
3 min:	70–75%
4 min:	75–80%
5 min:	80–85%
10 min:	85–90%.

- Has persistent central cyanosis or low oxygen saturation, despite free-flow oxygen increased to 100%.

Positive pressure ventilation can be provided with either a self-inflating bag (**Fig. 5**) or a T-piece resuscitator (**Fig. 6**). PPV is provided at a rate of about 40 breaths/min. In term babies, PPV should be initiated with room air and then titrated based on oximetry readings. In preterm babies too it is advisable to initiate PPV with room air and then subsequently titrate with pulse oximetry readings. The baby should be assessed for effectiveness of PPV after 30 s of the procedure.

**Effective ventilation** Prompt increase in heart rate, appearance of spontaneous breathing efforts, improvement in color and muscle tone are good indicators of effectiveness of PPV. If the baby

**Figure 5** Self-inflating bag with oxygen tubing and reservoir

Source: Reprinted with permission from National Neonatology Forum (NNF), India.

**Figure 6** T-piece resuscitator

Abbreviation: PEEP, positive end-expiratory pressure.

Source: Reprinted with permission from National Neonatology Forum (NNF), India.

requires less than 1 min of PPV, then further care can be provided by observing with the mother. *PPV can be stopped when baby has good spontaneous breathing efforts and has a heart rate greater than 100 beats/min.*

**Not improving** If the baby is not improving, i.e., no spontaneous breathing or no rise in heart rate, the following actions should be considered based on the assessment of the baby.

- *If the heart rate is more than 60 beats/min but less than 100 beats/min* Continue PPV as long as the baby is improving and reassess every 30–40 sec.
- *If the baby's heart rate is below 60 beats/min despite 30 sec of effective PPV* Continue PPV, increase oxygen supplementation to 100% and consider initiating chest compressions.

## Chest Compressions

Chest compressions would need two health-care personnel. Chest compression should be coordinated with ventilation. If the baby has not been intubated, one should consider endotracheal intubation before initiating chest compressions. Chest compressions and ventilation should be provided in a ratio of 1:3 for at least 1 min before the baby is reassessed. Chest compressions are discontinued when heart rate goes above 60 beats/min. However, if the heart rate remains less than 60 beats/min, one must consider use of medications.

## Medications

**Epinephrine** Epinephrine is indicated when the heart rate does not go above 60 beats/min after PPV and chest compressions. It is administered intravenously in a dose of 0.1–0.3 mL/kg of a 1:10,000 solution.

**Volume expansion** Volume expansion should be considered in a baby in shock with evidence of blood loss (as in antepartum hemorrhage). Ringer's lactate or 0.9% saline can be used in dose of 10 mL/kg.

## Discontinuation of Resuscitation

If there is no heart rate despite of all the resuscitative steps outlined above or no progress is made in some situations as in the case of an extreme preterm, resuscitation efforts may be discontinued.

### IN A NUTSHELL

1. All neonates at birth must be provided essential newborn care.
2. Essential newborn care includes drying of baby, delayed cord clamping, skin-to-skin care, early initiation of breastfeeding, cord and eye care, vitamin K and weighing all newborns.
3. Neonatal resuscitation in the delivery room is indicated in babies who do breathe adequately at birth.
4. The steps of resuscitation include initial steps, PPV, chest compressions and medications.

## Chapter 12.2

# Assessment of the Newborn

Harish Chellani, Sugandha Arya

Assessment of a newborn, like any other age group involves detailed history and physical examination. In this chapter, we shall discuss assessment of an apparently well newborn in the first few days of life. The purpose of this assessment is to identify high-risk neonates for further management. Another important purpose is to identify common early neonatal problems which predominantly need only parental reassurance.

## HISTORY

History taking for assessment of a newborn not only involves postnatal history but also antenatal and intranatal history in detail as these factors have a significant impact on newborn's health. Most of the components of history can be obtained from mother and relatives but some of the components may need enquiring the obstetrician especially the details of labor and delivery. History taking for newborn assessment should include sociodemographic data, maternal medical history, family history (particularly for congenital malformations, metabolic disorders, hearing impairment and mental retardation), maternal obstetric history (including details of the present pregnancy particularly antepartum and intrapartum details) and details of the baby at and after birth (need for resuscitation, feeding and any neonatal morbidity and immunization).

## NEWBORN EXAMINATION

Newborn examination requires patience, gentleness and flexibility of routine. Overall visual and auditory appraisal of the naked newborn offers more information than careful organ examination. Baby should be naked particularly during initial examination but should not be kept uncovered for more than a minute or two as neonates may easily become hypothermic particularly in colder months. The baby should preferably be under a radiant warmer during examination. The examination of the newborn should preferably be carried out in the mother's presence as it helps in allaying her doubts and anxiety about the infant.

Adequate information during systemic examination is best obtained when the infant is asleep or in a state of quiet wakefulness; the crying infant can often be quietened by placing on the mother's lap and conducting a further examination in that position. To ensure continued cooperation of the baby during the examination, the examiner's hands must be warm and dry. The physical examination of the baby should be conducted soon after birth. This first examination is done to determine:

- Whether the baby has any congenital abnormalities (**Fig. 1**).
- To categorize the baby in the birthweight and gestational age groups to determine the level of care needed.
- To detect any other disorder which may affect the neonatal course and which may require urgent attention.

Following the initial examination, a detailed physical examination of the newborn should be conducted at 24 hours of age, as by this time, most infants have recovered from the physical stress of labor and can withstand greater handling. A further detailed physical examination is desirable before the baby is discharged from the hospital.

**Figure 1** Microcephaly (head circumference 29 cm) with congenital talipes equinovarus deformity in a term baby

## General Examination

### Initial Observation

The initial observations on the neonate should include:

- **Posture of the baby**—The full-term infant lies in an attitude of flexion similar to the position assumed in utero. The preterm infant usually lies in extended position.
- **Color**—Pallor may represent anemia, shock or hypoxia. Peripheral cyanosis may be present for a short while after birth even in normal neonates which disappear once the child's temperature is stabilized. The presence of jaundice should also be noted.
- **Cry**—Cry of a term neonate is vigorous. Feeble, soft or high-pitched cry is abnormal.

### Physiologic Parameters

**Temperature**—Routine temperature recording should be done by the axillary method. Axillary temperature recording is as good as rectal and safer than rectal with less risk of injury or infection. A digital thermometer needs to be switched on for recording the temperature. It is recorded by placing the bulb of thermometer against the roof of the dry axilla, free from moisture. The baby's arm is held close to the baby to keep the thermometer in place (**Fig. 2**). The temperature is read when the thermometer beeps. If mercury thermometer is used, then the temperature is read after 5 min. Normal axillary temperature is 36.5–37.5°C. Rectal temperature recording is not done routinely. However, it is the best guide for

**Figure 2** Recording the temperature in newborn

core temperature in cold sick neonates. The baby's temperature can be reliably assessed by human touch. The warm and pink feet of the baby indicate that the baby is in thermal comfort.

**Respiratory rate, heart rate and capillary refill time**—These are discussed later along with the examination of cardiorespiratory system.

### Anthropometry

All neonates should have the following anthropometric measurements recorded:

- **Weight** Weight should be recorded accurately using an electronic weighing machine. If electronic weighing machine is not available, then use beam balance or spring balance. Babies weighing less than 2,500 g are called low birthweight babies.
- **Length** Length should be measured on an infantometer taking care that knees are fully extended and the feet are perpendicular to the horizontal (**Fig. 3**). Length of a term neonate at birth is about 45–50 cm.
- **Head circumference** This is measured at the level of the supraorbital ridges and maximal parietal prominences (**Fig. 4**). The head circumference of term newborn is about 33–35 cm and should be recorded 24–48 hours after birth to obviate the effects of birthing process on the skull.

### Gestational Assessment

Gestational assessment by physical and neurologic criteria needs to be carried out in all babies where the date of the last menstrual period of the mother is not known or unreliable. Soon after birth, assessment of gestation is to be made by using physical criteria as the newborn may not be in an optimal state for neurologic examination. Physical features in a newborn which suggest prematurity (i.e., gestation period of less than 37 weeks) are detailed in the **Box 1**. After 24 hours of age, as baby stabilizes, detailed gestational assessment using both physical and neuromuscular criteria can be done by various scoring methods, e.g., *expanded new Ballard's scoring* or *Dubowitz*

**Figure 3** Measuring the length of the newborn using an infantometer

**Figure 4** Measuring the head circumference of the newborn

### BOX 1 Physical criteria for assessing gestation

- **Deep sole creases** are absent or are limited to anterior one-third of the sole
- **Genitalia** Testes are at the external ring. Scrotum is small with few rugosities. Labia in female infants are widely separated with prominent clitoris
- **Breast nodule** is less than 5 mm in diameter or not perceptible. It may also be small in term growth retarded babies
- **Ear cartilage** is deficient and has poor elastic recoil
- **Skin** is smooth, pink with visible veins. Fuzzy or wooly hair called lanugo may be present.

*scoring*. Expanded *New Ballard's scoring* (**Box 2**) is widely used in practice and its video demonstration is available at [www.ballardscore.com](http://www.ballardscore.com).

**Neuromuscular maturity** Details of maneuvers for assessing gestation using neuromuscular criteria are summarized below.

- **Posture** Observe the infant in supine position. Observe the degree of flexion of upper limbs and lower limbs and score according to the criteria one is using.
- **Square window** Flex the hand of the baby on his forearm between your thumb and index finger (**Fig. 5**). Apply enough pressure to get as full flexion as possible and measure the angle between the hypothenar eminence and the ventral aspect of the forearm and score accordingly.
- **Arm recoil** With the infant in supine position, flex the forearms for 5 sec, and then fully extend at the side of the trunk by pulling on the hands, and then release. Observe the degree of flexion at elbows after the release.
- **Popliteal angle** With the infant in supine position and his pelvis flat on the table, hold the thigh in knee-chest position by your left index finger and thumb supporting the knee. Then extend the leg by gentle pressure from your right index finger behind the ankle (**Fig. 6**) and measure the popliteal angle in this position.
- **Scarf sign** With the baby supine, take the baby's hand and try to put it around the neck and as far as possible around the opposite shoulder (**Fig. 7**). Observe how far the elbow is going across the midline.
- **Heel to ear** With the baby supine, draw the baby's foot as near to the head as it will go without forcing it (**Fig. 8**). Observe the distance between the foot and the head and the degree of flexion at the knee joint.

### Skull

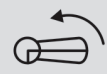

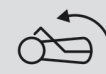

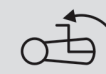

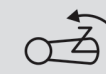

The skull should be examined for abnormal shape (as in craniosynostosis), sutural separation (for hydrocephalus) and abnormal swelling (e.g., cephalohematoma, encephalocele). One must assess the size of the anterior fontanel (normal size is  $20 \pm 10$  mm); very small anterior fontanel may indicate craniosynostosis or be seen in microcephalic heads, while large fontanelle may indicate hydrocephalus (if associated with sutural separation) or insufficient membranous ossification as seen in growth-retarded neonates or congenital vitamin D deficiency. Hydranencephaly if suspected can be detected by transillumination of the skull. Any significant and persistent abnormality in shape or size of the skull should be evaluated by cranial tomography.

### Eyes

Attempts to force open the eyelids of a newborn are likely to result in failure. Gentle tilting of the head back and forth (doll's eye maneuver) will succeed in opening the newborn's eyes. The

**Figure 7** Scarf sign

**Figure 8** Heel to ear. Note that the pelvis is fixed and the thigh is flexed parallel to the trunk. The foot is held by the examiner and the leg extended as far as possible to measure the distance from the ear

eyes should be carefully examined for jaundice, subconjunctival hemorrhage, iris abnormalities, or any other corneal abnormality. Examine for opacity which may be due to cataract, or corneal injury or dystrophy. If the cataract is posterior, it is detected by absence of red reflex on ophthalmoscopy.

### Mouth

The mouth should be examined for cleft palate, deciduous teeth and retention cysts. Extraction of deciduous teeth is usually not indicated. On the hard palate on either side of raphe, there may be accumulation of epithelial cells known as *Epstein pearls*. Both retention cysts and *Epstein pearls* disappear spontaneously within few weeks of birth.

### Ears

Evidence of external ear malformation may be a marker of associated renal anomalies. Hearing impairment is a serious disorder which affects speech and development. Universal screening of all newborns is recommended to ensure early detection of hearing impairment for timely intervention. The infants who are at high risk of hearing loss include those with ear malformations, family history of deafness, birthweight less than 1,500 g, had evidence of bilirubin encephalopathy, infants who required exchange transfusion for hyperbilirubinemia or who had meningitis or birth asphyxia.

### Skin

The skin of a preterm neonate is thin and pink unlike that of a term neonate in whom it is paler. Loose wrinkled skin with peeling suggests intrauterine malnutrition or postmaturity. Parchment like skin with peeling may be seen in congenital ichthyosis. An extraordinary division of the body from forehead to pubis into red and pale halves is harlequin color change, a transient and harmless condition.

### Developmental Dysplasia of Hip

It should be ruled out in all newborns. Each hip should be examined separately. There are two ways of doing it:

1. **Ortolani test** With newborn supine on the examining table, place the index and middle fingers along the greater trochanter and place the thumb on the medial aspect of the thigh. Stabilize the pelvis by placing the thumb and ring finger of the opposite hand on top of both anterior iliac crests simultaneously (**Fig. 9**). Flex the hip to 90° and abduct while lifting the leg with hip in neutral external or internal rotation. If a palpable clunk is felt as the dislocated femoral head reduces into the acetabulum, it indicates developmental dysplasia of hip.
2. **Barlow test** In this test, we try to dislocate or subluxate a located but unstable hip. Hold the thigh and stabilize the pelvis in the same way as in Ortolani's test. With hip in neutral external or internal rotation and at 90° of flexion, adduct the leg with mild posteriorly directed pressure applied to the knee. If a palpable clunk is felt, it indicates developmental dysplasia of hip.

Abnormal intrauterine posture can result in what appears to be a *talipes deformity*. If feet can be dorsiflexed to the extent that dorsum of foot touches the tibial skin, this excludes a pathological talipes equinovarus deformity. If developmental dysplasia of hip or pathological talipes deformity is suspected, the newborn infant should be referred to an orthopedic surgeon for further evaluation and management.

### Spine

The spine must be examined for presence of tuft of hair, pigmentation, lipoma or hemangioma (as these may indicate an occult spina bifida), meningocele—or meningomyelocele (**Fig. 10**) or a pilonidal sinus.

**Figure 9** Ortolani's maneuver: The limb is in adducted position with the examiner's thumb on the lesser trochanter and the fingers supporting the greater trochanter. The pelvis is supported on the opposite side by the other hand

**Figure 10** A neonate with *meningocele* in the lumbar region with a tuft of hair

## Systemic Examination

### Cardiorespiratory System

**Respiratory rate** The respiratory rate of a newborn is normally between 40 breaths/min and 60 breaths/min. Auscultation and percussion of chest are of limited diagnostic value in a newborn. As a general rule, if the infant has good color and no respiratory distress, there is unlikely to be a major cardiorespiratory problem. The severity of respiratory distress may be assessed by the presence or absence of tachypnea (RR > 60 breaths/min) or by the presence or absence of use of accessory muscles and nasal flaring. There are different scoring systems to assess the respiratory distress in a newborn—*Silverman score*, *Downe's score*, *ACoRN score* (**Table 1**).

Note for any abnormal bulge in either hemithorax or in the supraclavicular region. If heart sounds are better heard on right side, this may be due to dextrocardia or shift of heart to right side. Shift of heart may be due to pneumothorax or diaphragmatic hernia. Transillumination of the chest may suggest the presence of pneumothorax. In case of a diaphragmatic hernia, the abdomen is usually scaphoid and bowel sounds may be auscultated in the chest.

Normally the breath sounds are bronchovesicular. If there is suspicion of pulmonary pathology because of respiratory distress or diminished breath sounds, obtain a chest radiograph.

**Heart rate** The heart rate in a newborn may vary normally from 120 beats/min in relaxed sleep to 160 beats/min during activity. The femoral pulses should always be palpated to exclude coarctation of aorta. Murmurs heard in the newborn period may be transient while significant heart disease may exist in the absence of murmur.

**Blood pressure** needs to be recorded only in sick neonates. It may be recorded by auscultatory method if stethoscope head is small enough. The Doppler method, using a transducer in the cuff can

accurately measure systolic and diastolic pressure. Noninvasive blood pressure monitors based on oscillometry also give accurate results. Palpatory and flush methods only give systolic pressure. The normal blood pressure in a neonate has wide range, systolic 50–80 mm Hg and diastolic 25–50 mm Hg.

**Capillary refill time** Good perfusion signifies adequacy of circulation. Poor perfusion indicates hypotension. A simple and reliable clinical indicator of perfusion is capillary refill time (CRT). To measure CRT, the skin over the mid-sternum or forehead is pressed with a finger for 5 sec so that it blanches. The finger is then lifted and time taken for refilling of the capillaries and return to original skin color is noted. Normal CRT is 3 sec or less. CRT may also be prolonged due to hypothermia because of peripheral vasoconstriction.

### Abdomen

The abdominal shape may offer important clues to underlying problems. A scaphoid abdomen suggests the presence of diaphragmatic hernia, a fullness in the flank may indicate a renal mass and a tense distended abdomen at birth may indicate intrauterine intestinal perforation, commonly due to meconium ileus.

The umbilicus should be examined soon after birth for the presence of two umbilical arteries and one umbilical vein. A single umbilical artery is usually associated with presence of other congenital malformations. In subsequent examinations of the umbilicus, one should look for umbilical hernia, granuloma or evidence of infection (erythema, induration or seropurulent discharge).

The liver in the newborn is normally about 2–2.5 cm below the right costal margin. The tip of the spleen may be normally palpable. Remember that there may be situs inversus. Both kidneys are usually palpable during the first 2 days of life. Large palpable kidneys may be due to cystic or hydronephrotic changes or a tumor (e.g., nephroblastoma).

**Genitalia** Phimosis in the newborn is invariably physiologic and needs no intervention. Hypospadias is a condition in which urethral opening is on the ventral surface of the penile shaft (**Fig. 11**). The ideal age for repair of hypospadias in a healthy infant is 6–12 months. A hydrocele in the newborn mostly disappears spontaneously during the first 1 or 2 years of life. The testes should be palpated for their presence in the scrotal sac. In females the labia must be parted and examined for imperforate hymen or vaginal cysts. Disorder of sex development should be suspected in the following situations: Bilateral cryptorchidism, unilateral cryptorchidism with hypospadias, penoscrotal or perineoscrotal hypospadias even if both testes are descended, apparently female genitalia with enlarged clitoris or inguinal hernia or asymmetry of labioscrotal folds, or cloacal exstrophy.

**Esophagus and anus** The esophagus and anus should be checked for patency in all neonates at birth in the labor room. The infant should be examined for esophageal patency by passing an orogastric tube. If mother has history of polyhydramnios or there

**Table 1** ACoRN scoring system for respiratory distress in newborn

Score	Respiratory rate	Cyanosis	Air entry	Grunt	Retraction	Prematurity
0	< 60 breaths/min	Nil	Normal	None	Nil	≥ 34 weeks
1	60–80 breaths/min	In room air	Mild decrease	Audible with stethoscope	Mild	30–34 weeks
2	> 80 breaths/min	In > 40% FiO <sub>2</sub>	Marked decrease	Audible with unaided ear	Moderate	< 30 weeks

Note: A score of more than 8 indicates need for ventilatory assistance.

**Figure 11** Penile hypospadias

**Figure 12** Rooting reflex in a newborn

is frothing or excessive salivation, one should suspect esophageal atresia. Rule out anal atresia by inspecting the anal opening at the normal site.

### Neurologic Examination

Probably the most reliable information that can be obtained regarding neurological status is while handling the baby during the preceding physical examination. Symmetry of movements, body tone, posture and response to handling can be evaluated while examining other organs. To reliably interpret the results of the newborn neurologic examination, the baby should be more than 24 hours of age and should be examined about 1 hour after a feed when baby is likely to be in an appropriate state of quite wakefulness.

**Alertness and spontaneous movements** The neonate's state of alertness—sleeping, quite wakefulness or crying should be noted. Absence of spontaneous movements in one or more limbs should prompt further examination, e.g., Erb's palsy usually revealed by lack of motion of the shoulder and arm; the arm will lie beside the body in response rather than being normally flexed with fist near mouth.

**Cry** Newborn's cry is probably one of the most sensitive indicators of neurologic well-being. The intensity and pitch should be noted. A high-pitched cry may suggest raised intracranial pressure seen in babies with severe birth asphyxia or meningitis. Seventh nerve palsy can also be detected (mouth drawn to one side) while the baby is crying.

**Neonatal reflexes** A number of primitive neonatal reflexes can be elicited in a healthy term neonate. Absence of reflex responses indicates general depression, central or peripheral motor dysfunction.

- **Sucking and rooting reflexes** When the nipple of breast or finger is brought into contact with infant's cheek, he seeks the nipple or finger (rooting reflex) (**Fig. 12**). Stimulation of the upper and lower lips produces movement of the lip and tongue in the direction of the stimulus (sucking reflex). Sucking reflex is feeble in the sick and preterm infants.
- **Moro's reflex** To elicit the Moro's reflex, hold the baby at an angle of about 45° from the table and then suddenly let the head fall back a short way. Alternatively, baby is placed supine and the back of the head is supported on the palm of the hand an inch or so above the table. Rapid release of the hand causes sudden movement of the cervical region which initiates the reflex as it is a vestibular reflex. The response consists of abduction and extension of the arms. The hands open but the fingers remain curved (**Fig. 13**). This phase

**Figure 13** Eliciting Moro's reflex

is followed by adduction of the arms. The response is also accompanied by crying, extension of the trunk and head with movement of legs. Infants with cerebral damage have exaggerated or absent response. An asymmetric response is seen in Erb's palsy, spastic hemiplegia and fracture of the humerus or clavicle.

If the above neurological screening is normal, there is rarely a need for detailed neurologic examination of the newborn.

## COMMON PHYSIOLOGICAL NEONATAL PROBLEMS

Most mothers do observe their babies carefully and are often worried about minor physical peculiarities or problems, which are of no serious consequence. She must be adequately informed and appropriately advised regarding minor problems to prevent undue anxiety of the mother.

**Regurgitation of milk** Most of the neonates take out small amount of curdled milk soon after feed. Child is usually active and vomitus is never yellow or green colored and baby looks healthy. To decrease the problem, mother should be advised regarding burping after feed and reassured regarding benign nature of the problem.

**Transitional stools** It is the transition from meconium (sticky thick green or black stools passed during first 2-3 days of life) to the yellow homogenous stool of a breastfed infant and is physiological. It starts on the 3rd or 4th day of life, is yellowish green and may be watery and contains some mucus.

The frequency of stools is increased (up to 10–15/day) and usually decreases by 10 days of life. It must be differentiated from diarrhea as it causes neither pathological weight loss nor dehydration. Transitional stool requires no treatment except parental reassurance.

**Erythema toxicum** The rash usually appears on the 2nd or 3rd day of life. It is scattering of erythematous macules, papules and even vesicles. It occurs commonly over the trunk, face and extremities while palms and soles are spared. It is to be differentiated from pyoderma in the vesicular state. Microscopy reveals eosinophils in erythema toxicum and cultures of vesicular fluid are sterile. The rash disappears spontaneously in 1–3 days. Reassurance of parents is all the treatment that is required.

**Mongolian spots** They are pigmented lesions found at birth in more than 50% of black *Native American or Asian* infants and occasionally in white ones. The area most commonly involved is the lumbosacral region but occasionally in the upper back, shoulders, arms, buttock and legs may be involved. The lesions may be small or large, grayish-blue or bluish-black in color, irregularly shaped and always macular. The lesions need no treatment except reassurance to parents as they tend to disappear within 1st year of life.

**Neonatal jaundice** Jaundice is a common physical finding (manifesting as yellowness of the skin of the face) when the serum bilirubin level exceeds 5 mg/dL during 1st week of life. As the degree of jaundice increases, there is cephalopedal progression of jaundice. Jaundice should be considered nonphysiological if it has appeared within 24 hours of age, stains the palms and soles or persists beyond 10–14 days of life.

### IN A NUTSHELL

1. Assessment of a newborn requires detailed antenatal, natal and postnatal history.
2. Obtain details of labor and delivery from obstetrician or obstetric records.
3. Examination of a newborn should be done in a warm room with warm hands.
4. There should be flexibility of routine and examination may not be done in a particular sequence.
5. Visual and auditory appraisal gives more information than detailed systemic examination.
6. Percussion and auscultation are of limited diagnostic value in newborns.
7. High-risk newborns should be identified for further examination and management.
8. Thorough search for minor and major malformations should be done.
9. Reassure parents regarding common minor or transient neonatal problems.
10. Plan any appropriate investigations required depending on history and examination findings for further assessment.

## Chapter 12.3

# Care of the Normal Newborn

Somashekhar Nimbalkar

Neonatal mortality accounts for more than 50% of the under-5 mortality in the South-East Asian region and India contributes to the maximum number of deaths. Most of these deaths occur in neonates who are high-risk, but faulty caregiving practices can result in morbidity and resultant death in some cases even amongst normal newborn infants [those who are term gestation with birthweights more than 2,500 g and who did not need care in a neonatal intensive care unit (NICU) for normal transition after birth]. This chapter would attempt to address the routine care of the newborn infant beyond the delivery room and during the first few days of life.

### WHERE SHOULD THE NORMAL INFANT BE CARED?

Normal newborn infants should always be roomed-in with their mothers (*Rooming-in* refers to care of newborn with its mother and not in a separate nursery). The normal newborn infants are to be placed in skin-to-skin contact with the mother (*Kangaroo position*). Some facilities place the infant in separate cot/bassinet adjacent to the mother's bed. The advantages of rooming-in are depicted in **Box 1**.

#### BOX 1 Advantages of rooming-in

- Leads to improved bonding, as mother is always available to care for her infant
- Encourages and improves exclusive breastfeeding
- Reduces the chances of infection
- Reduces the chances of hypothermia and promotes *Kangaroo* mother care
- Improves the mother's confidence in caring for her baby
- It reduces the need for nursing personnel to care for the infant.

It is safe for a newborn infant to sleep with its mother. Some mothers may want rest and sleep after delivery and may express a desire to have the baby separated for some time. This should be discouraged; mothers and their families should be counseled on the advantages of rooming-in.

### CLOTHING THE BABY

A great deal of thermal control can be achieved by bedding in and *Kangaroo* mother care. In many regions of India, there are cultural practices related to clothing. As a result of these cultural taboos, newborn infants are often left unclothed for several hours or days, except may be for a thin piece of cloth, which places the infant at increased risk of hypothermia. It then becomes the responsibility of the healthcare provider to ensure adequate provision of *Kangaroo* mother care in the interim and counsel the family about the need of adequate clothing. In tropical conditions, a newborn infant would need a cotton vest and a loosely fitting gown that ties at the back with a disposable or washable diaper. If the temperatures are cold, they would need additional layers of woolen caps, socks and blankets to keep them warm when not in skin-to-skin contact. Newborn clothing should not be tight; they should be loose and comfortable to wear and warm.

### BABY IDENTIFICATION

Quality guidelines require patient identification to be a cornerstone of patient safety in hospitals. Neonates and mothers should have separate registered hospital numbers but their identification tags should be similar. The baby identification tag should have its hospital number, gender, date of birth, its mother's name and mother's hospital identification number. Additional details may be required as per individual hospital policy or existent state regulations. Tags should be placed in the infant's wrist or ankle and preferably made of soft plastic material which will not tear and are amenable to cleaning. Bar coding of tags may be considered if resources are available.

### FEEDING THE BABY

The newborn infant should be breastfed soon after birth in the delivery room. Thereafter it is important that mothers exclusively breastfeed their newborn infants on a demand schedule and offer no prelacteal or other feeds. As families get nuclear, most mothers are not in the know of the required skills of breastfeeding. Most mothers would want to breastfeed their babies and healthcare providers should help them successfully establish breastfeeding and not assume that they have the required skills. Early initiation of breastfeeding has great benefits and this should be ensured by healthcare providers. Imparting skills to mothers and family is important. Rooming-in mother and baby would ensure successful breastfeeding. It is equally important to counsel mothers to take of her own health as it would impact lactation.

### BATHING THE BABY

Neonates should not be given a bath soon after birth especially to remove the vernix. Vernix should not be removed as it protects the newborn skin and would get removed on its own over the first few days. Apart from chances of cross-infection, the preparation for a bath often makes the infant susceptible for hypothermia. The only exception for this may be when the infant is covered with blood. If the bath water is maintained at 36°C, then infant comfort is maximum and heat loss is avoided. A bathing routine initiated after 7th day of life does not impact the skin barrier or its environmental adaptation. A daily bath is not required especially if thermal environment cannot be managed. Washing and drying the groins, genital and buttocks every time the diaper is changed is sufficient. Soap is not required and should never be used on newborn's face. Alkaline soaps do increase the pH of the skin and do interfere with the function and development of the acid mantle. Mild synthetic detergents do not cause any adverse events and are akin to plain water. Bathing does not influence healing of the umbilical cord or skin microflora colonization which occurs in the first 2–3 days of life. However, it is important that where possible mothers may be taught how to bathe their infants before discharge from the hospital. It is important to emphasize that the room must be warm and the infant dried immediately after the bath.

In the Indian subcontinent often massage with oil is given before bath in most homes. The oil utilized varies by region and its health effects are not studied. However often during this process oil may be blown into the infant's nose/ear, which is not safe and should be avoided.

### CORD CARE

The current evidence recommends dry cord care with no application of medication on the cord. Napkins when used

should be folded well below the umbilical stump. The length of the stump should be such that it is not easily soiled by urine or stool. The cord falls off by the end of the 1st week and this separation is mediated by inflammatory processes at the junction with abdominal skin. At the time of separation the cord can be seen as moist, sticky and smelly and may show cloudy mucoid material which may be misinterpreted as pus. Alcohol (70% isopropyl alcohol) should not be used for application to the cord in the hope that it will keep the cord dry as this causes a delay of separation by 1–2 days than dry cord care. The same results occur with application of antiseptics.

## EYE CARE

There is no role of routine antimicrobial prophylaxis. In case there is discharge due to conjunctivitis antibiotic drops are to be instilled. Sometimes unilateral eye discharge can occur due to obstruction of the nasolacrimal duct. Caregivers should be taught massage of the middle canthus to resolve this issue over the course of the month.

## STOOLING PATTERN

Parents are often concerned by the stools that the neonate passes. A delay in passage of stools beyond 24 hours should initiate measures for evaluation as almost all neonates pass stools by 24 hours of life. Most neonates pass stools after each feed. The gastrocolic reflex is well preserved and every time the stomach becomes full, the ileocecal valve relaxes initiating a bowel movement. This is often interpreted as indigestion and this concern needs to be addressed as the mother may doubt her suitability of her breastmilk for the infant. Parents should be counseled regarding the transitional stooling pattern, its frequency (which may be up to 10–12 times/day) and consistency that may be loose and persist up to even 3 weeks.

## URINATION

The term neonate should pass urine by 48 hours of life with 95% neonates passing urine within 24 hours of life. A delay in voiding beyond 24 hours should alert the physician to renal and postrenal causes of delayed voiding. Almost 15% neonates void at the time of delivery and care should be taken to ensure that this is recorded. A normal renal ultrasound (prenatal) in association with a normal physical examination and passage of urine by 72 hours should preclude further testing. The neonate is expected to pass urine at least 6 times/day after the 3rd day of life. Frequency less than that may be reason to evaluate if the infant is receiving adequate breastmilk. The nappies are sometimes stained pink due to urate crystals and this does not require any intervention.

## PHYSICAL EXAMINATION

This is described in detail in the previous chapter. Assessments are done immediately after birth to rule out detectable malformations which can be life-threatening. Anthropometry, particularly weight and head circumference, is of special importance and needs to be recorded and also conveyed to parents. Detailed daily physical examination is not necessary unless the baby is unwell or parents have specific complaints. However it is advisable, if at discharge a detailed examination is done and recorded for future reference.

*Weight pattern* Newborns should not be weighed everyday. They should be weighed at birth and if still in hospital then between the 3rd and 5th day of life and at discharge. Normal newborns

lose about 7–10% of their birthweight in the first few days and regain their weight by 7–10 days of life. When infants do not regain birthweight, one must evaluate adequacy of milk intake by the infant. After the initial weight loss, they gain weight at the rate of about 25 g each day.

## PREVENTION OF INFECTION

The caregivers should wash their hands before touching or caring for the baby. They should also wash their hands after changing diaper or napkin. After removal of the diaper, it should be disposed of in a bucket or plastic bag which can be closed. Sick children and adults should be kept away from the newborn.

## IMMUNIZATION

Hepatitis B should be administered as early as possible after birth while Bacillus Calmette Guerin (BCG) and oral poliovirus vaccine (OPV) before hospital discharge. A dose of hepatitis B vaccine given within 12 hours of birth can prevent vertical transmission by 75–90%. Before discharge there should be brief discussion of various vaccines that will be administered over the following years. This should include a reference to the immunization card and the cost of vaccines if any. A detailed discussion of vaccines can be deferred to the first or second postnatal visit in the first fortnight after delivery.

## COMMON NEONATAL PROBLEMS

*Vaginal discharge* Many female infants have a mucoid/bloodstained vaginal discharge in the first few days after delivery due to withdrawal of maternal hormones. If noticed during examination, it is prudent to draw the attention of the relatives to this and explain how to clean the area and keep it dry and reassure them about the temporary nature of the discharge.

*Breast enlargement* Neonates of either gender can have enlargement of breasts due to influence of maternal hormones. There might be milk secretion too. They can remain enlarged for even a month. Parents should be counseled against squeezing/massaging them.

*Nasal block and sneezing* The newly born neonate can sneeze due to external fluid blocking the nose. Also the small size of the nose makes it susceptible for blockage due to collection of mucoid secretions. The neonate usually clears this by sneezing and multiple sneezes should not cause concern. Often this is interpreted as cold and one must avoid using medications for the same. Prescribing normal saline to clear the nose works well if it affects baby's feeding/sleep.

*Behaviors that are normal* Yawning, hiccups, passing wind, straining with bowel movements, crying before urination, trembling of chin, quivering of lips, burping, startle reflex, clearing of throat, gurgling sounds, trembling and jitteriness of arms and legs while crying are all normal. Often the breathing patterns can induce anxiety. Newborns can take rapid, progressively deeper breaths, or have long pauses (< 6 sec) without turning blue. Noises can be caused by movements or breathing during sleep.

*Fever* If the newborn develops fever in the 1st week of life, it is usually attributable to infection or overheating due to environmental temperature. However, if these are ruled out, then dehydration fever should be considered in the setting of loss of more than 10% of birthweight and a well-appearing baby. Plasma osmolality will be more than 310 mOsmol/L. Ensuring increased fluid intake in the form of frequent breastfeeding will result in normalization of the temperature.

## NEWBORN SCREENING

**Hearing assessment** Congenital hearing loss affects about 3–4 infants per 1,000 livebirths. Detection of hearing loss in neonatal period and early infancy allows targeted management which can improve hearing outcomes. Strategies for newborn hearing screening vary but a two-step process with a specificity of 0.99 is commonly used. Automated otoacoustic emission (OAE) screening initially followed by auditory brainstem response in those who fail is often the preferred approach. Parents need to be counseled about the importance of not missing these screens, as early intervention including cochlear implants has improved outcomes.

**Newborn metabolic screening (NBS)** Screening newborns for inborn errors of metabolism is mandatory in most developed countries. In many states of India, NBS has been introduced in large public hospitals and many private hospitals also offer NBS. The tests offered in NBS vary with laboratories and the technologies used for NBS also vary. Tandem mass spectroscopy is most commonly used for NBS. Few drops of blood are collected from the heel of the newborn on a special filter paper after day 1 and usually on day 3, these dried blood spots are transported via regular mail to the laboratories. Reports are usually dispatched by a week. NBS is usually done for common disorders such as hypothyroidism, phenylketonuria, galactosemia, glucose-6-phosphate dehydrogenase (G-6-PD) deficiency and congenital adrenal hyperplasia. Positive screening tests need to be confirmed by using confirmatory tests to eliminate false positive results. Infants with confirmed tests would need to be put on appropriate treatment at the earliest. For details, see Chapter 3.19.

## DISCHARGING A NORMAL NEWBORN

A normal newborn should ideally be discharged after 72–96 hours after delivery if it is free from any illness including significant jaundice, immunized, has a mother who is breastfeeding confidently and the mother is healthy. At times parents insist on discharge within 24 hours. In such cases the infant should be followed up between 3 days and 5 days of life to check for breastfeeding establishment and development of any jaundice. At discharge all mothers should be given a road to health card which has the details of the baby's birthweight and immunization details.

**Sleeping position** It is recommended that neonate be placed on the back, on a firm mattress, without any compressible material in the sleeping area to prevent accidental suffocation.

**Car seats** In urban areas, parents should be informed about the use of car seats for neonates and infants. These seats must always be rear facing and strapped onto the back-seat of the car.

**Washing clothes** Laundry detergents containing fragrances and dyes should be avoided while washing clothes of newborn infants. Additional rinsing should be advised to remove all detergents.

**Communication with family** Communication with family should begin before the delivery and continue during the delivery process and in the postnatal period too. Most parents are very receptive to messages during the postpartum period. However, mothers may be in pain, and exhausted and sometimes not in a position to receive advice. Hence, instead of standardizing time of communication it should be adjusted to when the parents are likely to receive it well. Since parents with healthy newborns will receive advice which is

generic, it may be better to deliver it to the extended family as well. This allows grandparents to interact and resolve queries.

In the Indian milieu, decision-making is often done not by parents but by grandparents and extended family and hence getting them involved is in the best interest of the newborn. Using multimedia and videos has shown to improve receptiveness of advice and it also allows parents to receive it at a time that suits them. Daily communication should also emphasize on breastfeeding, infection control, thermal management and the health of the mother. She should be told that if the baby cries she should respond by picking up the baby, talking to it, establishing eye-to-eye contact and addressing the cause of crying (messy diaper, hunger, etc). This should usually stop crying and the newborn will gaze at the mother. These repeated interactions promote infant and maternal bonding and hence mother should be encouraged to carry out most of the care of their babies. It is to be emphasized that most mothers are anxious and may not have understood all messages that were given in the first few meetings. Hence, emphasizing the elements of baby care on an everyday basis will improve the understanding of the mother. It will also empower her to ask questions which she may have hesitated to ask on the first few days. Communication at discharge should be detailed with advice on immunization, baby care and danger signs (**Table 1**).

## POSTPARTUM DEPRESSION

Postpartum depression is quite common and occurs in about 10% of mothers. It is different from postpartum blues that may occur in the first week of life and it has serious consequences for the care of the newborn and infant through the 1st year of life. Postpartum depression can interfere with maternal-infant bonding, adversely affect cognitive and language development in the infant and, hence, needs to be detected by the pediatrician during the postpartum visits by the mother. Simple screening tools such as *Edinburgh Postpartum Depression Scale* are available to detect it and have been validated in many Indian languages. Postpartum depression can be well managed by various available therapies, such as pharmacotherapy, psychotherapy or their combinations.

Care of the normal newborn involves less of diagnosis and more of anticipation and counseling. Combining art and science skillfully to advise new parents to ensure adequate care of the

**Table 1** Danger signs in a neonate

- Breathing less than or equal to 30 or more than or equal to 60 breaths/min, grunting, severe chest indrawing, blue tongue and lips, or gasping.
- Refusal to feed or suck at breast
- Feels cold to touch or axillary temperature less than 35°C
- Feels hot to touch or axillary temperature equal to or greater than 37.5°C
- Red swollen eyelids and pus discharge from the eyes
- Convulsion/fits/seizures
- Jaundice/yellow skin (at age less than 24 hours or more than two weeks) involving soles of the feet and palms of the hands.
- Pallor
- Bleeding
- Repeated vomiting, swollen abdomen, no stool after 24 hours

newborn is the endpoint that needs to be achieved. The timing of this care allows physicians the window of opportunity to bring about adoption of appropriate healthcare practices by parents which has a far-reaching impact on the life of the newborn.

### IN A NUTSHELL

1. Mother and newborn infant should always be roomed-in after birth.
2. Bathing the newborn should be deferred to end of 1st week.
3. Umbilical cord should be left dry; no applications should be made in a healthy cord.
4. *Kangaroo mother care* should be encouraged in the 1st week.
5. Newborn babies should be discharged only if they are breastfeeding well, have no major illness and have been immunized.
6. During hospital stay and at discharge communicate with parents and extended family regards care of the infant at home.

## Chapter 12.4

# Maintenance of Temperature

Suksham Jain, Ravish Singhal

The human newborn is a homeothermic mammal but has a limited capacity to maintain its core temperature against adverse environmental conditions because they are not able to generate adequate shivering response. During pregnancy, maternal mechanisms transfer heat from placenta to the fetus and maintain intrauterine temperature, keeping it 0.3–0.5°C higher than that of the mother.

Incidence of hypothermia in neonatal period in various studies in India (temperature < 35–35.6°C) has been reported up to 17% and it increases to 48% when a temperature less than 36°C was used to define hypothermia. Hypothermia in neonates is more due to lack of awareness of keeping the infant warm than due to lack of technology. Even during resuscitation more emphasis is given to achieving adequate oxygenation and cardiac output, and temperature is often overlooked. Hypothermia can result in poor somatic growth, and severe hypothermia can even lead to death.

### PHYSIOLOGY OF THERMAL CONTROL

After birth, the neonate is exposed to a hostile extrauterine environmental temperature. The newborn moves from an ambient intrauterine temperature of 37–25°C as air replaces the intrauterine amniotic fluid in which the baby was surrounded. As the amniotic fluid on the skin surface begins to evaporative soon after birth, there is a tremendous heat loss at the rate of 0.58 kcal/mL of water lost. This brings into play mechanisms that attempt to maintain the body temperature in the euthermic range. It is important to understand that temperature is a balance between mechanism of heat production and heat loss which can be summarized in the following equation:

$$\text{Temperature} = [\text{Heat production}] - [\text{Heat loss due to (evaporation + convection + radiation + conduction)}]$$

### Heat Production

When an infant is exposed to cold or heat, the temperature is sensed through peripheral thermal receptors which are found

over the entire surface of the skin, and as a first response leads to dermal vasoconstriction. At the same time central thermoreceptors are also stimulated and these send signals to the hypothalamic regulatory center. Efferent signals from the hypothalamic nuclei result in an increase in sympathetic activity and this action results in the release of norepinephrine from the diffuse innervation at the surface of brown adipose tissue and the stimulation of thyroid-stimulating hormone release, which in turn stimulates a rise in thyroxine levels from the thyroid gland. The released norepinephrine activates monodeiodinase, which converts thyroxine to triiodothyronine, which upregulates the production of an uncoupling protein (thermogenin) in the brown adipose tissue. Brown tissue is present in axilla, perinephric, interscapular, medistinal and paraspinal areas. It acts as a source of nonshivering thermogenesis (**Flow chart 1**) and second sympathetic effector organ. The uncoupling of mitochondrial oxidation from phosphorylation results in heat production from oxidation of free fatty acids, and the uncoupling of adenosine triphosphate synthetase. At the same time signals are also sent via the thalamus to the cerebral cortex, resulting in conscious perception of the change in environment, leading to changes in behavior and increased movement.

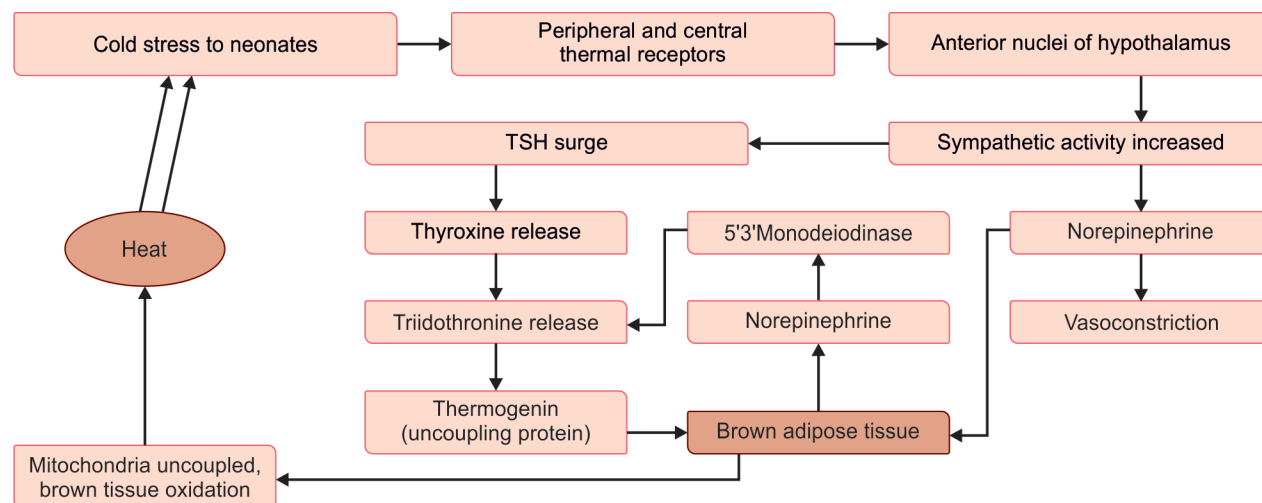

Preterm neonates are functionally poikilothermic due to some handicaps (**Box 1**). In the absence of external heat source due to ineffective heat production, they start losing temperature at a rate of 0.3–1°C/min and in the immediate postnatal period a wet preterm neonate may lose heat at a rate of 200 kcal/kg/min or greater.

### Heat Loss (Fig. 1)

#### Evaporation

This mechanism is most common source of heat loss at birth. Preterm transcutaneous evaporation of water in preterm babies is higher as compared to term babies and this results in higher evaporative heat loss. This is because preterm babies have poorer keratinization of stratum corneum that offers less resistance to diffusion of water. Heat loss in these babies is nearly 15 times more than a term neonate. Even a dry infant has evaporative losses in an environment with low humidity. Postnatally the skin matures rapidly so that by 2–3 weeks even the most immature babies have evaporative losses comparable to term babies.

Flow chart 1 Nonshivering thermogenesis

Abbreviation: TSH, thyroid stimulating hormone.

**BOX 1 Handicaps of preterm newborn in temperature regulation**

- Skin surface area to weight ratio is higher, in extremely preterm neonates heat dissipating area is five to sixfold greater than adults
- Less subcutaneous fat, hence, decreased thermal insulation
- Decreased heat production due to less brown fat, less uncoupling protein, thermogenin, less monodeiodinase in less than 32 weeks gestation babies
- Babies do not shiver like adults to generate heat, because muscle constriction-relaxation fibers are not yet myelinated
- Increased transepidermal water loss due to highly permeable skin, especially in extreme premature neonates
- Less glycogen stores in premature neonates and intrauterine growth retarded babies
- Caloric intake for thermogenesis and growth is limited in neonates and it is gestational age-dependent
- Oxygen consumption is limited in presence of pulmonary problems.

**Figure 1** Mechanism of heat loss in neonates**Convection**

Heat loss by this mechanism depends on the air speed and temperature difference between baby and its surroundings. It is a major source of heat loss in newborns exposed to cold, draughty environment.

**Radiation**

Heat is lost by radiation from the exposed surface of the baby to the surroundings depending upon the temperature difference, via infrared electromagnetic waves. Infant's posture affects radiant

heat loss, with more flexed posture reducing the exposed area and decreasing heat loss.

**Conduction**

Heat is lost to the cooler surface in contact with infant's skin. Heat loss is proportionate to difference in temperature of the baby and the cold object. However, due to use of insulating mattresses and blankets, this mechanism plays minimal role in neonatal heat loss.

**Definitions**

**Euthermia** Axillary temperature of 36.5–37.5°C or skin temperature of 36–36.5°C.

**Hypothermia** Temperature below 36.5°C. **Table 1** provides the grading for severity of hypothermia. Hypothermia frequently occurs in the following settings:

- Cold environment and low humidity
- Naked baby, cold linen and bathing in cold room
- Blood sampling, surgery and infusions
- Neonatal transportation.

**THERMAL NEUTRAL ENVIRONMENT**

Critical importance of environmental temperature on outcome and survival of newborn infants can be better understood by examining the effects on its metabolism. Hill defined a set of thermal conditions under which oxygen consumption is minimal even as body temperature is maintained in the normal range. *Thermoneutral environment* is an age and gestation-based band of environmental temperature wherein the infant's body temperature is maintained at minimal basal metabolic rate (measured by oxygen consumption). It allows calories to be used for growth and development rather than using them for thermoregulation. **Table 2** provides details of the thermoneutral temperature zones.

**TEMPERATURE ASSESSMENT**

- **Touch** Warm hands and feet indicate normal temperature, warm abdomen and cold extremities suggest cold stress; cold abdomen and extremities suggest moderate to severe hypothermia.
- **Thermometer** World Health Organization recommends use of low reading thermometer up to 30°C. Rectal temperature is measured by inserting the bulb up to a depth of 3 cm in term and 2 cm in preterm babies. It gives best idea of the core temperature. Axillary temperature is measured by placing the bulb high up in axilla and holding the thermometer perpendicular to the adducted arm.

**Table 1** Severity of hypothermia (WHO 1997)

Grade of hypothermia	Axillary temperature	Skin temperature
Mild hypothermia or cold stress	36–36.4°C (96.8–97.5°F)	35.5–35.9°C
Moderate hypothermia	32–35.9°C (89.6–96.6°F)	31.5–35.4°C
Severe hypothermia	<32°C (89.6°F)	<31.5°C

**Table 2** Thermoneutral zone for neonates

Birthweight	Environment temperature			
	35°C	34°C	33°C	32°C
<1,500 g	1–10 days	11 days to 3 weeks	3–5 weeks	After 5 weeks
1,500–1,999 g		1–10 days	11 days to 4 weeks	After 4 weeks
2,000–2,499 g		1–2 days	3 days to 3 weeks	After 3 weeks
≥2,500 g			1–2 days	After 2 days

Source: Hey et al., 1969.

- **Thermistor** Skin temperature is measured by a thermistor probe placed over abdomen in supine and flanks in prone position. False high readings are possible due to applying probe over interscapular region (area of brown fat), sandwiched between skin and mattress or due to tight fitting cloths. False low reading is possible in cases of loose probe attachment or probe placed over bony prominences.
- **Liquid crystal thermometry—thermospot** It has a 12 mm liquid crystal temperature dot which is placed on the newborn's skin, medial to and just above axilla. It turns black if baby is hypothermic and green if baby is eutermic. This simple method is most appropriate for use in community settings.

## CLINICAL SIGNS OF HYPOTHERMIA

- **Initial signs** Due to peripheral vasoconstriction in response to hypothermia, the skin may become pale, extremities feel cold, there may be acral cyanosis, and poor peripheral perfusion. Infants may appear irritable at this stage.
- **Later signs** If hypothermia persists, the infant may manifest with apnea, bradycardia, hypotonia, lethargy, weak cry and suck, abdominal distension, emesis and central cyanosis.
- **Prolonged hypothermia** If hypothermia is prolonged, the clinical manifestations could include hypoglycemia (due to increased metabolism and glucose consumption), hypoxemia and metabolic acidosis due to secondary anaerobic metabolism, which can result and be compounded decreased pulmonary blood flow due to increased pulmonary vascular resistance causing persistent pulmonary hypertension. Other features that could be seen include peripheral and facial edema, sclerema, subcutaneous necrosis, acute renal failure, necrotizing enterocolitis, coagulation defects, all of which could result in death. If the infant is jaundiced, there is increased risk of bilirubin encephalopathy due to acidemia and elevation of nonesterified fatty acids which compete with bilirubin for albumin-binding sites.
- **Chronic cold stress** The features are less dramatic and may manifest only as poor weight gain and/or progressive weight loss.

## PREVENTION OF HYPOTHERMIA

Pierre Budin, a French obstetrician, focused on temperature and thermal regulation. Silverman in the late 1950s and early 1960s reported the impact of temperature and humidity on neonatal outcome. It was noted that higher humidity also caused higher infant temperature, and improved survival.

### Warm Chain

The warm chain is a set of ten interlinked steps carried out at birth and later which will reduce the chances of hypothermia in all newborns:

1. **Warm delivery room (25–28°C)** After birth, newborn's temperature can drop at a rate of 0.1–0.3°C/min for core and skin temperature respectively. Delivery room needs to be prepared much in advance. The delivery room should be warm (at least 25–28°C) using heat convectors or heater (objective recording of room temperature may be done by using room thermometer), free from draughts from open windows and doors or from fans. One should avoid using air conditioners in summers/high-speed ceiling fans.
2. **Warm resuscitation corner (28°C)** The radiant warmer in the resuscitation corner should be switched on at least 20–30 minutes in advance and put into manual mode with 100% heater output.
3. **Immediate drying** After birth, the baby should be immediately dried with a dry towel, starting with the head. After drying thoroughly, the baby should then be covered with a second, dry towel and a cap put on its head. All linen should be pre-warmed.
4. **Skin-to-skin contact** Baby can be placed prone on mother's chest in skin contact after delivery even during delivery of placenta, and episiotomy suturing. Later on also skin-to-skin contact should be promoted in wards, during transportation and at home in all preterm babies for a minimum period of 4–6 hours per day.
5. **Breastfeeding** Breastfeeding should begin as soon as possible after birth, preferably within an hour.
6. **Bathing/weighing postponement** Bathing should be postponed in a term baby at least till next day. It is better to avoid bathing in hospital. Weighing should be done only after covering the baby adequately and making zero correction for clothing.
7. **Clothing and bedding** Newborns should be covered with one or two layers of clothes and in colder climate there should also be a cap, socks and hand gloves.
8. **Rooming in** In postnatal wards, babies and mother should be allowed to be together in the same bed and breastfed on demand.
9. **Warm transportation** In case of transport, whether to home, to another hospital/another section, thermal protection should be ensured.
  - All peripheral hospitals caring for high-risk mothers should go for in utero transfer as early as possible.
  - Stable babies including preterm and low birthweight babies should be transported well-wrapped and in skin-to-skin contact with mother.
  - Very low birthweight, unstable, admitted babies should be transported using an incubator. Temperature should be checked before and after transport.
10. **Training and awareness** All the health-care personnel involved in the newborn care should be adequately trained in maintenance of body temperature of baby as per steps of warm chain.

## Thermal Management in Preterm Neonates

### Polythene Occlusive Wraps

Recent resuscitation guidelines recommend use of polythene wraps for all babies less than 28 weeks. Baby after birth should be immediately brought under radiant warmer and wrapped in polythene bag below the neck without drying. Wrapping delivers radiant heat to baby while decreasing evaporative losses.

### Incubators (Fig. 2)

These are preferred over radiant warmers because insensible water loss is decreased and infant's temperature is regulated by controlling the air circulation. Evaporation losses are limited by using maximum relative humidity and radiation losses are minimized by double walls in the incubators. It has two modes of temperature control—air and skin servo mode. In air mode, desired environment temperature is set from the charts and heater output adjusts itself to reach that air temperature. This mode is preferred during procedures or when baby is stable and can be transferred to cot. In skin servo mode a skin sensor is attached to baby and temperature is set to 36.5°C. Heater output adjusts to keep baby constantly at this temperature. It is preferred in sick babies. Humidity is usually adjusted to provide 80–85% humidity. Humidifier chambers should be filled with sterile water only and should be changed daily, otherwise chances of infection can increase.

### Radiant Warmers (Fig. 3)

This system is good for babies more than 1,800 g as it allows easy access for procedures, but at the cost of increased insensible water loss. Heat is uniformly reflected onto the surface. They reduce conductive heat loss by warming the microenvironment. It has two modes, skin servo and manual mode. Baby is preferably kept on skin servo mode, where temperature is set at 36.5°C. Heater output adjusts to maintain this set temperature. Baby may get over-or underheated, so only one baby should be nursed in a warmer bassinet, and always check temperature every 15–30 minutes.

In case of preterm neonates, a cling wrap can be used across the walls of radiant warmer to decrease insensible water losses. When baby is nursed under a radiant warmer/incubator, head and legs should be covered, and clothed when stable.

### Kangaroo Mother Care (Fig. 4)

It has been the most effective, low cost method of temperature maintenance for a hemodynamically stable preterm neonate. It not only helps in thermal regulation but also facilitates breastfeeding, helps

in better cardiorespiratory stability, less infection rate, increased mother-baby bonding, better weight gain and early neonatal intensive care unit (NICU) discharge, and improved survival.

## MANAGEMENT OF HYPOTHERMIA

In all babies who are detected to have hypothermia, blood sugar must be estimated to check for hypoglycemia. It is also important to note that neonates with sepsis may also manifest with hypothermia, therefore in all babies with moderate to severe hypothermia, a sepsis screen must be done and if baby is unwell, antibiotics may be initiated after taking a blood culture. **Box 2** summarizes the management principles for a hypothermic newborn.

## HYPERTEHRMIA

It is defined as a temperature of more than 37.5°C. The causes of hyperthermia in the newborn are listed below:

- Environmental
- Over clothing, wrapping baby in too many layers especially in hot, humid climate
- Dehydration fever usually results from excess weight loss, presenting on day 3–4 of postnatal life; fever generally subsides with correction of breastfeeding problems or when extra feeds given properly
- Sepsis.

### Clinical Features

Baby is usually irritable and later becomes lethargic, has tachycardia, tachypnea, and a hot flushed face. Severe forms of hyperthermia can lead to shock, convulsions, even death in neglected cases.

### Management

Place the baby in a normal environment (25–28°C) away from heat source. Undress the baby partial/fully. Monitor hydration, weight, urine output and renal function. Give frequent breastfeeds. Give breastmilk or by *katori* and spoon if needed. Correct dehydration, if any. If temperature is more than 39°C, sponge can be done with tap water. While doing so do not use cold/ice water. Monitor temperature hourly till it becomes normal.

**Figure 2** Incubator for thermal maintenance

**Figure 3** Radiant warmer for thermal protection

**Figure 4** Kangaroo mother care for thermal protection

**BOX 2 Management principles for hypothermia****Mild hypothermia**

- Skin-to-skin contact
- Cover adequately
- Warm room
- Prevent heat loss by using radiant warmers, incubators, oil application, warm mattress
- Identify and treat the cause
- Monitor axillary temperature every 30 minutes

**Moderate to severe hypothermia/failure of re-warming in mild hypothermia/progressively falling temperature**

- Ensure no further heat loss, remove cold, wet clothes and cover baby adequately with prewarmed clothes
- Rapid re-warming till baby is 34°C (set radiant warmer manual mode—heater output 100%; skin mode, 36.5°C; incubator air mode, 38–39°C)
- Monitor vitals, skin temperature continuously and axillary every 30 minutes
- Oxygen and ventilation to maintain SpO<sub>2</sub>
- Inject vitamin K
- Intravenous fluid, maintain hydration and blood sugar
- Monitor blood pressure, urine output, renal function and serum electrolytes
- Monitor bilirubin.

**IN A NUTSHELL**

1. Neonates are prone to hypothermia due to limited capacity of thermal regulation, large body surface area and less subcutaneous fat.
2. Heat production is mainly restricted to nonshivering thermogenesis, which is poorly regulated in preterm neonates due to less brown fat.
3. Heat loss in neonates occurs by four main mechanisms: conduction, convection, evaporation and radiation.
4. In normothermic baby, both abdomen and feet are warm to touch.
5. Prevent hypothermia at all the levels: in delivery room, in postnatal wards, at home and during transportation, by training health personnel.
6. Special measures to be taken in preterm neonates in form of polythene occlusive wraps before drying in labor room, use of double-walled incubators, radiant warmers, skin-to-skin contact (kangaroo mother care).
7. Moderate to severe hypothermia is to be managed in NICU.
8. Hyperthermia in neonates may occur more commonly due to overclothing, raised environmental temperature and dehydration.

## Chapter 12.5

# Breastfeeding and Lactation Management

NB Mathur

Exclusive breastfeeding is the most effective intervention to reduce infant mortality and is estimated to prevent 13% of under-5 child mortality in low-income countries. Supporting a breastfeeding mother can be time-consuming initially but pays off in a healthier population. Breastfeeding rates are influenced by socioeconomic factors, education and support services. Health professionals have a responsibility to prepare mothers for breastfeeding and promote and protect breastfeeding practices in the society. Recommended infant feeding practices include (i) timely initiation of breastfeeding within half an hour of normal delivery and within 4 hours of cesarean section; (ii) exclusive breastfeeding up to 6 months; (iii) timely initiation of complementary feeds at 6 months; and (iv) continuing breastfeeding well into the second year of life.

### TERMINOLOGY

**Exclusive breastfeeding** If an infant is fed no other food or drink except breastmilk, it is exclusive breastfeeding. The baby should not have been given even water or a pacifier.

**Predominant breastfeeding** If a breastfed infant is fed small amounts of another food or drink, such as water, or tea but is predominantly breastfed, it is almost exclusively breastfeeding or predominantly breastfeeding.

**Partial breastfeeding** If a baby has some breastfeeds and some artificial milk feeds, or other drinks; or has started supplementary feeds but continues to be breastfed, it is called partial breastfeeding.

**Token breastfeeding** If an infant mostly has other food, but still breastfeeds occasionally, it is called token breastfeeding.

**Bottle-feeding** This means feeding a baby from a bottle even if the feed is expressed breastmilk.

### TYPES OF BREASTMILK

#### Colostrum

Colostrum is secreted as early as second trimester and during the first week after delivery. It is thick, sticky and yellowish or clear in color. Colostrum contains large quantities of protective, anti-infective and growth factors and has more protein and vitamins A and K than mature milk. It should never be discarded. It enhances the development and maturation of the baby's gastro-intestinal tract. The anti-infective proteins and white cells provide the first immunization against the diseases that a baby encounters after delivery. Although colostrum is secreted in small quantities, it is sufficient to meet the caloric needs of a normal newborn in the first few days of life. Colostrum also has a mild purgative effect, which helps to clear baby's gut of meconium and helps to prevent jaundice by clearing the bilirubin from the gut. Being rich in growth factors, it stimulates the baby's immature intestine to develop in order to digest and absorb milk and to prevent the absorption of undigested protein. If a baby is given any other milk or food before colostrum, it can damage the intestinal mucosa and cause allergies.

#### Transition Milk

During the first 2 weeks, the breast secretions increase in quantity, change in appearance and composition and are called transition

milk. The immunoglobulins and protein contents decrease while fat and sugar contents increase.

#### Mature Milk

Mature milk increases in quantity and contains all the nutrients needed for healthy physical and mental development of the baby. The composition of mature milk changes even during a single feed to exactly suit the needs of a baby. The milk that comes at the start of a feed is called foremilk. *Foremilk*, which is watery, has a low level of fat and is high in lactose, sugar, protein, vitamins, minerals and water. It satisfies the baby's thirst and is produced in larger amounts than hindmilk. Mothers sometimes worry that their milk is too thin and need reassurance. It is important for a baby to have foremilk and hindmilk to get a complete meal and all the water and calories that the baby needs. Pooled breastmilk is predominantly foremilk and has poor caloric value. It is also heat treated which affects its anti-infective value adversely, *hindmilk* is richer in fat and whiter than foremilk. It satisfies the baby's hunger and supplies energy. There is, however, no sudden change from foremilk to hindmilk. The fat content increases gradually from the beginning to the end of a feed.

#### Preterm Milk

Milk produced by a woman who has delivered prematurely is called *preterm milk*. This milk has more protein, minerals, immunoglobulins, lactoferrin, lysozyme, and cells than term milk. Preterm milk is suited for the survival and growth of a preterm baby.

### BENEFITS OF BREASTFEEDING

Breastfeeding is economical, convenient and physiological. Breastmilk is rich in essential fatty acids, lactose, long chain polyunsaturated fats and phospholipids. It also supplies enzymes including amylase, lipoprotein lipase and lacto-peroxidases. These enzymes increase digestibility and also act as defense against microbes. Long-chain polyunsaturated fats promote brain growth and reduce the risk of dyslexia and hyperactivity. Biochemically breastmilk is superior to artificial milk. The protein in breastmilk is predominantly whey protein (80%) and is rich in  $\alpha$ -lactoglobulin and lactoferrin. Lactalbumin is rich in tryptophan, a precursor of serotonin which plays an important role as a neurotransmitter. Lactoferrin ensures absorption of iron and zinc is bacteriostatic. Breastfeeding ensures transfer of maternal antibodies and T-lymphocytes and provides protection against some infectious diseases. Exclusively breastfed babies have been shown to have higher intelligence quotient and may have higher mathematical abilities than artificially fed babies. They are also less prone to asthma and other allergic disorders later in life. Breastfeeding not only benefits the baby but is advantageous to the mother as well. Breastfeeding reduces postpartum bleeding, promotes early uterine involution and helps in spacing of children and early resorption of excessive fat. It has a protective effect against breast and ovarian cancers as well. Mothers who exclusively breastfeed their babies are better adjusted with their babies as far as rearing and behavior adjustments are concerned.

### MILK PRODUCTION: PROLACTIN REFLEX

As the baby suckles on the breast it provides a sensory stimulus through nerve endings in the nipple and areola to the anterior pituitary glands resulting in the prolactin release through the prolactin reflex. This acts on glands in the breast for milk production. Prolactin is important determinant of milk volume. While baby suckles, milk is transferred under the influence of oxytocin. If a baby sucks the nipple and areola more, the milk production increases. If

a baby suckles less, milk production will fall. For the same reason, if a mother has twins, breastmilk production can double due to increased suckling. Relatively more prolactin is produced in response to suckling at night.

### MILK FLOW: OXYTOCIN REFLEX

Stimulation of sensory nerves in the nipple and areola by suckling also induces the secretion of oxytocin, from the posterior pituitary gland (the oxytocin reflex). Oxytocin acts on the muscle cells around the alveoli causing the ejection of milk. If it does not work well, the baby may have difficulty in getting the milk. It may seem that breast is not producing milk, although in fact it is there but not flowing. Oxytocin reflex may not be very prompt in some mothers, particularly preemies and may require 1–3 min of suckling for the response. Oxytocin also makes the uterus contract and controls postpartum bleeding. Oxytocin release is affected by the mother's emotional state. Positive emotions, particularly thinking lovingly of her baby and feeling confident of being able to breastfeed, can facilitate oxytocin reflex. The sight of the baby and the sounds made by the baby help augment the oxytocin reflex. Negative emotions like pain, worry, lack of confidence and doubt about her ability to produce milk inhibit the reflex. It is important that health professionals refrain from making adverse comments that could cause worry and undermine the self-confidence of the mother.

### SUCCESSFUL LACTATION

Breastfeeding should be initiated as soon as possible after birth, and definitely within 1 hour. In Cesarean section the breastfeeding should be initiated as soon as the mother recovers from the effect of anesthesia and mostly within 4 hours of birth. In the first 1–2 days the requirements of the babies are little, and are met with even a few minutes of suckling at the breast. The key to the successful initiation of lactation is frequent and regular suckling at the breast by the baby, on demand, and in the correct position. The baby should be kept with the mother to ensure good initiation of breastfeeding. No prelacteal feeds should be allowed as they inhibit the establishment of successful lactation. Measures to ensure successful breastfeeding are summarized in **Boxes 1 and 2**.

### NEONATAL REFLEXES THAT SUPPORT BREASTFEEDING

*Rooting reflex* When nipple is touched around the mouth of the baby, the baby turns its mouth towards the stimulus and opens it. This indicates the baby's readiness to accept the breast or its need for a feed. This is the method to initiate breastfeeding.

#### BOX 1 Ten steps to successful breastfeeding

1. Have a written breastfeeding policy that is routinely communicated to all health-care staff
2. Train health-care staff in skills necessary to implement these policies.
3. Inform all pregnant women about benefits and management of breastfeeding
4. Help mothers initiate breastfeeding within half an hour of delivery
5. Show mothers how to breastfeed, and how to maintain lactation even if they are separated from their mother
6. Give newborns no food or drink other than breastmilk, unless medically indicated
7. Practice rooming-in, allow mothers and infants to stay together 24 hours a day
8. Encourage breastfeeding on demand
9. Give no artificial teats or pacifiers to breastfeeding infants
10. Foster establishment of breastfeeding support groups and refer mothers to them on discharge from hospital, clinic.

#### BOX 2 Measures to establish and maintain lactation in very low birthweight or preterm and sick infants in NICU

- Mother should be allowed free access to her neonate in the nursery
- She should be provided with a bed as long as the baby is admitted in the nursery
- She should be encouraged to take part in the general care of her baby
- She should be taught the correct method of manual expression of milk with emphasis on correct site of pressure (at the areolar margin and not squeezing the nipple)
- Manual expression may be encouraged 10–12 times in a day including at night. Babies should be put on breast after manual expression for non-nutritive sucking if initiation of breastfeeding is delayed owing to baby's illness
- Building a mother's confidence should be high priority and all situations that undermine her confidence should be avoided
- Breastfeeding should be a precondition for discharge
- All health-care staff should be trained in managing breastfeeding problems including inverted, cracked and sore nipples.

*Sucking reflex* As the baby accepts the breast (nipple and areola), he starts sucking on the breast. Any touch on the palate induces this reflex.

*Swallowing reflex* As milk is transferred and collects in the mouth, it is swallowed. This swallowing reflex develops early in fetal life but its coordination with sucking occurs only by 32–34 weeks of gestation. The coordination can be enhanced by repeated exposure to suckling.

### PROCESS OF BREASTFEEDING

#### Position of the Mother and Baby

A mother can feed her baby in any comfortable position, such as lying (supine and lateral) or sitting. While feeding in the sitting position, the mother should sit comfortably leaning against a backrest. The baby should be held with the mother's palm under the buttock, and the leg and arm under the back of the baby, leaving the head free and at the level of the breast. Baby's body should be close, facing breast. Baby's body should not be away from the mother as that would twist his neck. Feeding in the lying down position does not cause otitis media.

#### Signs of Good Attachment

These include baby's chin is close to the breast and is sucking around the areolar circumference, baby's mouth is wide open and the lower lip turned outwards, more areola is visible above the baby's mouth than below it. There should be no pain in the nipple area during breastfeeding. The baby should take nipple as well as areola inside the mouth for transfer of maximal quantities of milk into the mouth. When a baby is well attached, he uses suction to pull out the nipple and areola to form a teat. Hence, he can effectively suck even if the size of the nipple is small.

#### Signs of Poor/Incorrect Attachment

These include baby sucking only at the nipple, mouth is not wide open, and most of the areola is outside the mouth. Chin is away from the breast.

#### Causes of Faulty Positioning (Attachment)

*Use of feeding bottles* If we offer bottle-feed to a baby before offering breastfeed, it may often lead to ineffective suckling due to nipple confusion. The mechanism of sucking from a bottle is different from that on the breast. Babies who receive some bottle-

feeds do not open the mouth fully and suck only at the nipple leading to sore nipple.

*Inexperienced mothers* Primipara mother may have difficulty in having her baby well attached.

*Functional difficulty* When a baby is small or sick or the mother has breast engorgement, attachment may be faulty. If skilled help is not available, baby may not be well attached. Due to ineffective suckling milk transfer is inadequate. It can further lead on to breast engorgement, baby is not satisfied and cries a lot, mother loses confidence in her breastmilk supply, leading to suppression of oxytocin reflex, incomplete emptying of breast further leads to decreased milk production.

### Duration and Frequency of Suckling

Babies can fulfill their requirements by suckling over 5–10 min. The baby should be allowed to decide the duration of the feed. Every mother should be advised to feed the baby from one breast completely and then put the baby to the other breast so that the baby gets the hindmilk also.

### Demand Feeding

The child should be fed on demand. Initially, the demands are very frequent but by 1–2 weeks the frequency decreases. The baby should be fed as frequently and for as long as it wants to, even at night. Breastfeeding at night helps maintain the milk supply as more prolactin is secreted during suckling at night.

## PROBLEMS DURING BREASTFEEDING AND LACTATION MANAGEMENT

Frequently encountered problems include those related to the nipple, like flat or inverted nipples, sore nipples, or breast engorgement, mastitis and not enough milk.

### Normal and Flat Nipple

Normal nipples may often appear flat. The protractility test helps in assessment. The mother rolls the nipple between index finger and thumb. If it protracts out, it is normal. The length of the resting nipple is not important for breastfeeding. However, the areola and the breast tissue beneath should be capable of being pulled out to form the teat. The nipple is just a guide to show where the baby has to take the breast.

### Inverted Nipple

Occasionally a nipple does not protract and on attempting to pull out the nipple it goes deeper into the breast—this is an inverted nipple. Fortunately, true inverted nipples are rare. The nipple usually becomes more protractile during pregnancy and mother should be reassured that she will be able to breastfeed.

*How to treat inverted nipples during postnatal period* The woman with inverted nipples needs help before every feed during postnatal period. Nipple exercises and shields are of limited value.

*Procedure to correct inverted nipple* Cut the nozzle end of the syringe. Introduce the piston from the ragged cut end side and apply the other end over the nipple and pull the piston. Nipple would protrude into the syringe. Put the baby to breast. It helps the nipple to erect out and baby is able to suckle in the proper position. Nipple may retract back subsequently but doing the procedure each time over a period of few days would help to solve the problem.

### Engorgement of the Breast

Fullness of the breast is a frequent problem. However, milk flow continues and the baby can feed normally. If enough milk is not removed, engorgement of breasts may result. The engorged breast

is tight, shiny (because of edema) and very painful. Also the milk may stop flowing. The common factors causing engorgement of breasts are: poor emptying of breasts due to infrequent suckling, prelacteal feeds, delayed initiation and long intervals between feeds, bottle-feeding, and any restrictions on breastfeeding. The baby cannot feed in the correct position because of engorged and painful breast, while the mother avoids feeding because of pain; this leads to inadequate emptying, decreased production of milk and sometimes infection. Once engorgement occurs, the baby should be breastfed frequently followed by expression of breastmilk. The commonest error in management is to stop breastfeeding, which aggravates the condition.

### Blocked Duct

If the baby does not suck well on a particular segment of the breast, the milk blocks the lactiferous duct, leading to a painful hard swelling. This *blocked duct* is not associated with fever. Tight clothing may also cause blocked duct. Treatment of a blocked duct includes: (a) improving suckling/position—the baby should be fed frequently on the affected breast and in various suckling positions so as to improve the emptying; (b) massaging the lump towards the nipple to promote emptying of the breast; and (c) encouraging the mother to take rest and wear loose clothes.

### Mastitis

If the blockage of the duct or engorgement persists, infection may supervene. The breast becomes red, hot, tender and swollen (mastitis). If untreated, an abscess may form as a hot, tender and fluctuant swelling, often associated with fever. A breast abscess may occur sometimes without preceding mastitis. Treatment consists of rest, and expressing the milk frequently. Antibiotics should be started and paracetamol administered for pain and fever. Warm water fomentation may help alleviate pain. Incision and drainage of the abscess may be needed in advanced cases. Breastfeeding should be restarted from the infected breast as soon as possible.

### Cracked/Sore Nipples

If a baby is not well attached to the breast, he sucks on nipple, causing sore nipples. If feeding continues in a poor position, it may lead to a cracked nipple and later stasis may lead to mastitis and breast abscess. Oral thrush in the baby is another important cause but it usually develops after a few weeks of breastfeeding. To prevent soreness and cracking of the nipples, attention should be paid to teaching correct feeding position to the mother.

*Treatment* Correct the attachment and positioning of the baby. This provides immediate relief to the mother. Breastfeeding should be continued on the affected breast as it heals readily after correcting the suckling position. Medicated creams are best avoided as they may worsen the soreness and draw the attention away from the main problem. For oral thrush, gentian violet should be applied over the nipple as well as inside the baby's mouth. For cracked nipples, treatment consists of feeding in correct position, washing the nipple once daily only with water, exposure of nipple to air and sun as much as possible, application of hindmilk drop on the nipple after each feed.

### Not Enough Milk

One of the commonest reasons for introducing supplementary milk early and terminating breastfeeding is that mothers feel that they are not producing enough milk. Mothers often worry about the amount of milk they produce. Sometimes relatives, friends or health workers casually comment that the mother may not have enough milk. The mother's confidence in her ability to meet the baby's needs is easily undermined. Almost all mothers can produce

enough breastmilk for one or even two babies, provided the baby suckles effectively as often as needed.

Often mother perceives that her milk is insufficient even though the baby is growing well on exclusive breastfeeding. The amount of milk produced is determined by the amount that the baby needs, it increases when the baby suckles more and empties the breasts completely. Milk volume is not affected by maternal diet.

Sometimes, however, a baby does not get enough breastmilk. Usually this is because the baby is either not suckling enough, or is not suckling effectively. Poor mammary gland development or hormonal disturbances are rare causes of decreased breastmilk production.

Mothers who believe that they do not have enough breastmilk need help and support. First, decide whether the baby is getting enough milk or not. If the baby is not getting enough breastmilk, decide why. Decide how to help the mother and baby. If a baby passes urine more than 6 times a day, and the urine is light-colored, the baby is probably getting enough breastmilk. This is a useful sign for monitoring the adequacy of breastmilk. If the baby is not getting enough breastmilk, the reason could be infrequent breastfeeding will produce less prolactin and hence reduced milk production; no night feeding leads to less prolactin. Use of bottles may lead to nipple confusion and psychological factors in the mother. Lack of confidence in the mother reduces secretion of oxytocin. Poor let down gives the mother an impression that she has no milk. Poor emptying of breasts leads to less milk production. Starting supplementary feeds further undermines mother's confidence leading to suppressed oxytocin reflex.

Explain to the mother why her baby is not getting enough breastmilk and reassure her that she can produce as much milk as the baby needs. Restore the mother's confidence. Help the mother to improve her baby's attachment at the breast. The baby should be allowed to suckle more frequently (12 times in 24 hours). The baby should be allowed to suckle at both the breasts.

If the baby is less than 6 months old and the mother gives supplementary milk feeds, help her to reduce them. Follow-up daily until the baby is exclusively breastfed. The advantages of exclusive breastfeeding and the dangers of unnecessary supplements should be clearly explained to the mother.

### Manual Expression of Breastmilk

All mothers should learn to express their breastmilk to feed a low birthweight or sick baby, relieve engorgement, maintain the milk supply when the mother is ill, relieve leaking breasts, and for storing milk for the baby when the mother goes out to work.

#### Method of Expression

The areolar circumference should be pressed between the index finger and thumb so that the lactiferous sinuses beneath the areola are compressed. If the procedure is painful, the technique is wrong. The fingers should not slide along the skin nor should the nipple itself be squeezed. Expression should be done all along the areolar circumference to ensure expression from all the segments of the breasts. The breast should be expressed for at least 5 min until the flow slows. To express milk adequately, it may take up to 20 min. It is important not to attempt hurried expression.

## FEEDING IN SPECIAL SITUATIONS

### Full Term Twins

Reassure the mother that she can produce enough milk for two babies and remind her that the increased suckling induces the production of more milk. Help her to discover the best method for

feeding. One method of breastfeeding twins together is by holding the babies with their bodies and legs under the mother's arms. Another useful position is to hold the babies in the mother's arms with the hands in front. The mother should ensure that weaker twin gets enough hindmilk. The family's support is absolutely essential.

### Low Birthweight Babies

Babies are able to suckle and swallow from about 24 weeks of gestation, but they may not be able to coordinate these movements completely until above 32–34 weeks. It is important for babies to start suckling at the breast as soon as they are able to and this exposure enhances the coordination. Manual expression of milk should be started as early as possible at intervals of 2 hours both in the day and night so as to ensure a good supply of milk.

### Cleft Lip or Palate

Breastfeeding is difficult in babies with cleft palate and counseling is required. Some babies with a partial cleft palate learn to breastfeed, especially if the mother is encouraged and the baby breastfeeds in an upright sitting position.

### Jaundice

Neonatal jaundice is not a contraindication for breastfeeding, in fact, it can help by clearing meconium early from the gut and reduces jaundice. Breastfeeding should not be temporarily stopped as a routine to find the cause of jaundice.

### Cesarean Section

As soon as the mother recovers from the effect of anesthesia (usually 4–6 hours after general anesthesia), the baby should be breastfed. The mother would need help in positioning the baby initially. The baby should be kept with mother. She should feed in the position she is comfortable with.

### Drugs and Breastfeeding

To stop breastfeeding is more likely to be harmful than the drugs themselves. Anticancer drugs, antithyroid drugs, radioactive substances and repeated doses of ergot (one dose postpartum is not harmful) must definitely be avoided. Diazepam, barbiturates, thiazide diuretics decrease milk supply. Most other drugs are safe.

### Environmental Pollutants

Household pollutants such as pesticides may be present in the breastmilk if these are present in the environment. Breastfeeding is safe in the presence of these in breastmilk as the other foods or animal milk would be more heavily contaminated.

## ANTENATAL COUNSELING

Preparations for breastfeeding should start in the antenatal period. Group discussions should be supplemented by individual talks on the advantages of breastfeeding, benefits of colostrum and dangers of animal milk feeding. Mothers should be shown how milk comes in, why the baby needs to suck even if the breast is empty and what is the correct attachment. The nipples should be examined and the mother reassured that she is fully capable of breastfeeding. The technique of breastmilk expression should be demonstrated.

All new mothers feel more emotional and sensitive than usual, and they should be explained that these feelings are normal and will pass. The mother should be encouraged to relax and should be handled calmly and gently. Her fears should be alleviated and her confidence boosted. If she looks miserable or is ignoring the baby, she might need extra counseling.

## CONCLUSION

There is ample evidence to suggest that group and individual counseling is an effective tool to achieve exclusive breastfeeding. A breastfeeding mother may easily lose confidence or give in to pressures from family members and friends to give artificial feeds. Situations which lower the mother's confidence should be avoided to protect exclusive breastfeeding. Hence, effective antenatal counseling, encouraging early initiation of breastfeeding, effective communication, baby-friendly hospital practices and management of common breastfeeding problems are keys to improving exclusive breastfeeding.

### IN A NUTSHELL

1. Breastmilk is the most optimum nutrition for the newborn babies and young infants.
2. Breastfeeding must be initiated within 1 hour of birth.
3. Good attachment on the breast, good sucking by the baby and frequent feeding (at least 8 times in 24 hours) are essential for successful lactation.
4. In every mother-baby dyad, it must be ensured that breastfeeding has been established before discharge from the health facility.
5. In low birthweight babies and those infants who cannot suck well, expressed breastmilk should be provided to the infant.

# Section 13 DISORDERS OF WEIGHT AND GESTATION

**Section Editor** Siddarth Ramji

## Chapter 13.1

### Low Birthweight: Classification and Etiology

*Ruchi Nimish Nanavati*

The newborn health challenge faced by India is more voluminous, more diverse and more formidable than faced by any other country in the world as it contributes to the highest number of births and neonatal deaths in the world. India contributes to the largest number of low birthweight (LBW) infants born each year worldwide which is the single most important determinant of neonatal morbidity and mortality. The financial impact of LBW birth on the family and society is enormous in terms of the immediate neonatal intensive care and ongoing long-term health issues frequently experienced by this high risk group. Thus, LBW has emerged as a major public health concern worldwide and addressing it absolutely essential, if we hope to accelerate our progress toward Millennium Development Goal 4 as well as *Every Woman Every Child* initiative launched by UN Secretary General during the United Nations Millennium Development Goals Summit in 2010 aiming to save lives of 16 million women and children by 2015.

Newborn infant can be LBW (birthweight <2,500 g), because of suboptimal fetal growth commonly known as intrauterine growth retardation (IUGR) or fetal growth restriction (FGR), or due to prematurity (younger than 37 weeks of gestational age).

#### EPIDEMIOLOGY

*"Every Newborn"*, An Executive Summary for The Lancet's Series May 2014, highlights that worldwide annually 2.9 million newborn babies die and 2.6 million babies are stillborn. More than 75% of newborn deaths occur in south Asia and sub-Saharan Africa. In 2012, nine countries had a neonatal mortality rate (NMR) of more than 40 deaths per 1,000 livebirths; most countries were from sub-Saharan Africa. The day of birth is when 40% of all stillbirths and neonatal deaths occur. About three-quarters of all neonatal deaths occur during the first week of life, with 1 million babies dying on the day they are born. In 2012, complications from preterm births, intrapartum-related disorders or birth asphyxia, and infections (especially sepsis, meningitis, and pneumonia) were the main causes of neonatal deaths. Small babies face the highest risk of death in utero, during the neonatal period, and throughout childhood. More than 80% of neonatal deaths in sub-Saharan Africa and South Asia occur in small babies. Every year, an estimated 19 million newborn babies face life-threatening conditions, including preterm birth, intrapartum-related brain insults, severe bacterial infection, and pathological jaundice. At least 1.5 million newborn babies survive with long-term disabilities every year. Since 1990, under-5 deaths and maternal deaths have been halved worldwide owing to the Millennium Development Goals, however,

the average annual progress for reductions in NMR (2.0%) was much lower than the rate recorded for children aged 1–59 months (3.4%).

In India, 20% of world's infants, an awesome 27 million, are born every year. UNICEF's State of the World's children report cites 30% incidence of LBW in India. Overall estimates indicate that 8 million LBW infants are born in India every year or around 40% of the total of 20 million LBW babies born globally. The National Neonatal-Perinatal Database (NNPD) of the National Neonatology Forum of India reported data on 1,45,623 neonates born at 18 leading centers of the country for 2002–2003. The LBW incidence was 31.3%, 8.7% being less than 2,000 g and 3.4% less than 1,500 g. FGR incidence was 9.6%. Studies published by Bang et al. in 1999 and Rahmathullah et al. in 2003 revealed that over 80% of LBW neonates weigh between 2,000 g and 2,499 g, about 15% between 1,500 g and 1,999 g, and only 3% weigh less than 1,500 g. The Global Action Report on Preterm Birth 2012 states that worldwide 15 million babies were born preterm in 2010 and 1 million died as a result of their prematurity. Action report on Preterm Birth in India 2013 documents that the country accounts for 3.6 million, i.e., 24% of global preterm births and for 303,600 preterm deaths. India heads the list of 10 nations contributing to 60% of the world's premature deliveries. It is essential to recognize that in contrast to the high income countries, over three-fourth of LBW in India are full term. IUGR or FGR is the predominant cause of LBW in developing nations with higher LBW rates. Of preterm infants, 20–40% also have decreased growth for gestational age.

India also tops the list of 10 nations with highest neonatal death numbers. The LBW is the single most important etiology of neonatal morbidities and mortality. Nearly three-fourth of neonatal deaths and half of infant deaths occur amongst LBW infants. Complications of preterm birth are now single largest direct cause of neonatal deaths in the world responsible for 35% of the world's deaths a year, and the second most common cause of under-5 deaths after pneumonia. The NNPD reported 75% of neonatal deaths in infants less than 2,500 g. Various studies report that LBW infants between 1,500 g and 2,500 g contribute to a sizable proportion of total neonatal mortality. This group of infants is potentially salvageable in the home as well as in a first-level health facility using simple low-cost interventions. Even after the neonatal period, LBW remains vulnerable to malnutrition, recurrent infection, neurodevelopmental disabilities and death. The above facts highlight that LBW/preterm births are a major public health concern in our country. Research suggests that FGR results in anomalous programming of affected fetuses predisposing them to a variety of adult onset diseases such as obesity, diabetes, hypertension and coronary artery disease.

#### CLASSIFICATION OF LOW BIRTHWEIGHT

Low birthweight is a heterogeneous group consisting of infants born preterm (<37 completed weeks of gestation) and infants born at term but of reduced weight. Neonates can be classified as per birthweight or gestational age.

## Birthweight Classification

Birthweight is the first weight of a live or dead product of conception, taken after complete expulsion or extraction from its mother. This weight should be measured within 24 hours of birth, preferably within its first hour of life before significant postnatal weight loss has occurred.

- *Low birthweight*: Birthweight less than 2,500 g
- *High risk low birthweight (HRLBW)*: Birthweight less than 2,000 g
- *Very low birthweight (VLBW)*: Birthweight less than 1,500 g
- *Extremely low birthweight (ELBW)*: Birthweight less than 1,000 g
- *Micro premie*: Birthweight less than 800 g.

## Gestational Age Classification

The duration of gestation is measured from the first day of the last menstrual period. Gestational age is expressed in completed days or in completed weeks. This is considered physiologically more important than birthweight.

### Preterm

Neonates less than 37 completed weeks of gestation.

- *Extremely low gestational age neonate*: Neonates less than 28 weeks of gestation
- *Early preterm/very preterm*: Neonates less than 32 weeks of gestation
- *Moderate preterm*: Neonates between 32 weeks and 33 6/7 weeks of gestation
- *Late preterm*: Neonates between 34 weeks and 36 6/7 weeks of gestation.

### Term

Neonates from 37 completed weeks to less than 42 completed weeks of gestation.

- *Early term*: Neonates from 37 weeks to 38 6/7 weeks of gestation
- *Full term*: Neonates from 39 0/7 weeks to 40 6/7 weeks of gestation
- *Late term*: Neonates from 41 0/7 weeks to 41 6/7 weeks of gestation.

### Post-term

Neonates from 42 0/7 weeks of gestation and beyond.

## Birthweight and Gestational Age Classification Correlation

This has great clinical significance as it helps in anticipating immediate neonatal problems as well as in prognosticating short and long-term outcomes in neonatal population.

- *Small for gestational age (SGA)*: Birthweight less than 10th percentile for that period of gestation
  - *Appropriate for gestational age (AGA)*: Birthweight between 10th and 90th percentile for that period of gestation
  - *Large for gestational age (LGA)*: Birthweight more than 90th percentile for that period of gestation

Thus, a LBW baby could be preterm, term or post-term as well as AGA, SGA or LGA. For example, a baby born at 36 weeks of gestation weighing 1,400 g is described as late preterm VLBW SGA.

## ETIOLOGY

Fetal physiology and growth as well as maternal influence on the fetus are discussed in the earlier chapters. Fetal development is characterized by organized patterns of tissue and organ growth, differentiation, and maturation that are influenced by the maternal environment, uteroplacental function and the inherent genetic

growth potential of the fetus. The fetus depends on maternal nutrient intake and on maternal endogenous substrate stores as precursors for fetal tissue synthesis and as fuel for fetal oxidative metabolism. An adequate provision and effective placental transfer of substrates and oxygen, as well as an appropriate hormonal milieu are necessary for optimal fetal growth. Inherited regulatory factors within the fetal genotype affect nutrient use and thus influence fetal growth. Normally functioning placenta plays an important role for growing fetus being an organ of gaseous exchange and nutrition. Genetic potentials are usually determinants of early fetal growth. Nutritional and environmental problems affect the fetus when the requirements for tissue growth increase later in pregnancy.

The causes and origins of LBW seem much more complex and remain elusive. Although there seem to be differences in the relative incidence of IUGR and premature birth in different countries, risk factors associated with birth of an infant with LBW are similar. The LBW has been largely studied as single group only. The risk factors associated with LBW are given in **Table 1**.

## Maternal Factors

The prevalence of putative risk factors is very high in Indian population. Poor maternal nutrition, *too early, too frequent, and too many pregnancies* are the principle risk factors for LBW. Women with low income, prepregnancy weight less than 40–45 kg, a height less than 145 cm, insufficient nutrient intake, low weight gain during pregnancy and lack of antenatal care often produce LBW.

### Maternal Age

Extremes of maternal age are not conducive for optimum outcomes of pregnancies. In India, teenage pregnancy is an important public health issue. By the age of 15 years, 26% of females are married and by the age of 18 years, it rises to 54%. National Family Health Survey III data showed that 25–28% of women in Eastern India aged 15–19 years had already started childbearing. A study from Jabalpur revealed that adolescents accounted for 1.25% of total deliveries and most of them were shorter (<145 cm), lighter (<45 kg), anemic (Hb <9 g%) and had higher incidence of preterm deliveries, 27.7% compared to 13.1% in adult mothers.

### Maternal Education

National Family Health Survey II data showed that 58.2% of Indian mothers were illiterate. In the Bengaluru cohort study, a decreasing trend of IUGR was observed with increase in maternal education, ranging from 46% in women who had no schooling to 19% in women who had postgraduate education.

### Maternal Nutrition

Maternal weight before pregnancy and weight gain during pregnancy are two vital independent determinants of fetal growth. Appropriate weight gain during pregnancy is based on body mass index (BMI). A woman with a normal BMI of 19.8–26 may require a weight gain of 11.5–16 kg during pregnancy. A woman with lower BMI needs higher weight gain during pregnancy. Mean BMI values were lower in low per capita income households. Fetal requirements are easily met during the first trimester, however, as fetal growth accelerates in second trimester, the requirements increase and may not be met with if maternal diet is insufficient in calories. A mother who is deprived of calories, below critical caloric needs, and/or micronutrients during antenatal period is highly prone for LBW baby. Micronutrient deficiencies during pregnancy have serious implications on the developing fetus. The National Nutritional Monitoring Bureau reports that 50% of adult Indian rural population is suffering from some level of chronic energy deficiency (CED). Nearly 47% of adolescent women have BMI less

than 18.5, 11.4% are stunted. The odds ratio for LBW was found to be three times more in severe CED groups of mothers as compared to normal BMI groups. In one study, maternal weight gain during pregnancy was a critical determinant of birthweight; with every kilo weight gain during pregnancy, there was 8% reduction in LBW rate. Poor weight gain by 16 weeks' gestation is predictor of birth of a LBW infant. Poor nutrition may also reduce uterine blood flow, placental transport, and villus surface area. Analysis of the correlation matrix between the birthweight and maternal biosocial

and nutritional factors revealed that birthweight of a baby best correlated with the height and weight of the mother.

### Socioeconomic Status

It is a major determinant of and has a direct impact on maternal nutrition, hygiene, and antenatal care. Medical complications of pregnancy occur equally in all socioeconomic groups however many adverse practices, stress, misbeliefs that can hamper fetal well-being are more prevalent amongst the women of low socioeconomic strata of the society. A study from Chandigarh revealed that low per capita income in addition to low literacy level, birth order 2 and above and maternal age above 30 years were found to significantly increase LBW incidence.

### Lifestyle Factors

Stress and excessive physical work contribute to spontaneous preterm birth and are likely to be much higher in resource poor setting. A study from Odisha revealed that mothers who delivered preterm babies had significantly higher stressful life event scores. Excessive maternal activity during pregnancy was associated with smaller fetal size in rural population. Smoking, excessive alcohol consumption and drug addiction have been associated with increased risk of preterm birth. Cigarette smoking during pregnancy reduces eventual fetal birthweight, which is directly related to the number of cigarettes smoked.

### Medical and Obstetric Causes

The disease states which cause either uterine ischemia or hypoxia or both interfere with fetal growth. In India, 20% adolescent married females are moderately severe anemic which is an important risk factor for LBW. Chronic maternal hypertension adversely affects fetal growth especially if diastolic blood pressure is elevated. India has higher incidence of rheumatic heart disease, almost 17% of preterm births may be precipitated by such maternal illnesses. Women with pre-existing medical diseases such as kidney disease, asthma, interstitial lung disease or autoimmune disorders, may be unable to tolerate the pregnancy to term and premature delivery may be indicated for maternal safety. Pregnancy-induced hypertension adversely affects fetal well-being as well as growth through its action on uteroplacental circulation. It is important to note that clinical signs of edema, proteinuria, and hypertension may develop later. Abnormalities in Doppler flow velocity waveforms of the uterine artery are evident much before conventional fetal surveillance tests can detect fetal compromise. It affects 6–8% of pregnancies and has been reported to be responsible for 15–43% of preterm births. Mothers who have excessively low fasting blood glucose values and mothers whose blood glucose levels are insufficiently elevated after an oral glucose tolerance test are at risk of delivering an infant who is SGA. Advanced stages of maternal diabetes mellitus resulting in vascular insufficiency produce IUGR, despite the presence of maternal hyperglycemia. Mothers residing at high altitude have been described to have LBW. Drugs such as propranolol and other  $\beta$ -blocking agents and corticosteroids probably have a direct effect on the fetus. However, the mothers receiving these agents are expected to have chronic maternal illnesses which also can hamper fetal growth and well-being.

*Infection* plays an important role in preterm birth. Acute maternal illness, febrile illness, urinary tract infection, malaria, bacterial vaginosis, HIV are all associated with increased risk of preterm birth. Ascending intrauterine infection and inflammation causing cervical insufficiency and premature cervical shortening culminating into premature delivery is well-documented. Periodontal infection can be a reservoir for inflammatory mediators and increases the likelihood of preterm birth. Screening for urinary tract infection in antenatal clinic

followed by treatment of asymptomatic bacteriuria reduces the risk of LBW or preterm delivery by 40%.

### Placental Factors

Placental growth was poor in mothers who delivered LBW infants and was an independent risk factor for LBW in a community-based study. In maternal disorders, such as pregnancy-induced hypertension, pre-eclampsia, with compromised uteroplacental circulation, placental weight and volume also diminish. Significant additional amount of energy is needed for optimal metabolic, endocrine and gas exchanging functions of placenta essential for fetal growth and wellness. When placental insufficiency occurs, these functions are affected to a variable degree. Diminished placental growth adversely affects total nutrient transfer, whereas reduced placental production of chorionic somatomammotropin attenuates maternal mobilization of fuels to the fetus. Reduced placental energy production and protein synthesis limits active transport of amino acids and facilitative transport of glucose. Placenta previa, placenta accreta, vasa previa and placental abruption are associated with preterm births. Chronic abruption is frequently associated with FGR and cerebral palsy. The risk of recurrent abruption is significant ranging from 6% to 17% after first episode to 25% after second episode. Placental malformations are commonly seen in multiple gestations. As a result of arteriovenous interconnections in monochorionic twins, a twin who serves as the donor develops FGR.

### Fetal Factors

#### Genetic and Ethnic Factors

Genetic determinants of fetal growth are inherited from both parents. Maternal genetic factors influence fetus more as compared to paternal factors. Indian born women and women of Indian descent living in Western countries tend to have a lower mean birth weight and a higher LBW rate compared to their western counter parts. This effect persists into second generation even after adjusting for important confounders like socioeconomic status and literacy. This intergenerational effect partly explains the observation that mothers of infants of LBW were themselves neonates with LBW. It is known that fetuses with insulin resistance or decreased numbers of cells may be unable to grow despite adequate nutrient supply. Examples of fetuses with diminished cell numbers include fetuses affected by rubella embryopathy, autosomal trisomy, and other genetic causes of IUGR. Cytomegalovirus and rubella virus are the most important identifiable agents associated with marked FGR. After maternal viremia, both agents invade the placenta, producing varying degrees of villitis, and subsequently gain access to fetal tissues. Intracellular rubella virus inhibits cellular mitotic activity in addition to producing chromosomal breaks and subsequently cytotoxicity. In addition, this virus produces an obliterative angiopathy that compromises cell viability further. Cytomegalovirus also causes cytotoxicity, resulting in areas of focal tissue necrosis. These viral agents reduce cell number and subsequent birthweight by simultaneously inhibiting cell division and producing cell death. Chromosome disorders, such as trisomy 8, 13, 18, 21, are associated with FGR. Certain metabolic disorders, such as agenesis of pancreas, hypophosphatasia, phenylketonuria, etc., are associated with diminished birthweight. Cornelia de Lange syndrome, Meckel-Gruber syndrome, Potter syndrome, Prader-Willi syndrome, Rubinstein-Taybi syndrome, Williams syndrome as well as VATER/VACTERL anomalies are often associated with diminished birthweight.

### Multiple Gestations

The incidence of premature births in India is 21% and is still rising. Multiple pregnancies carry nearly 10 times the risk of preterm birth compared to singleton births. Approximately, 50–60% of twins, 90% of triplets are born preterm and virtually 100% of all higher multiple gestations result in preterm birth. Preterm birth can be classified into two broad subtypes: spontaneous preterm birth and provider-initiated preterm birth. Spontaneous preterm birth is a multifactorial process influenced by social and environmental factors, however the cause of spontaneous preterm labor remains unidentified in almost 50% cases. Maternal history of preterm birth is a strong risk factor driven by the interaction of genetic, epigenetic and environmental risk factors. A preterm first birth is the best predictor of a second preterm birth. Young or advanced maternal age, short interpregnancy intervals and low maternal BMI have been associated with an increased risk of spontaneous preterm birth. Another important risk factor is uterine over distension with multiple pregnancies. The uterus must have sufficient space for the fetus to grow. In multiple gestations, the uterine constraint seems to occur when combined fetal size approaches 3 kg. The number and causes of provider-initiated preterm birth are more variable. In a recent study in the USA, more than 50% of all provider-initiated preterm births at 34–36 weeks gestation were carried out in absence of a strong medical indication. Unintended preterm birth also can occur due to errors in gestational age assessment. Severe pre-eclampsia, placental abruption, uterine rupture, cholestasis, fetal distress and FGR with abnormal tests are some of the more important direct causes recognized. Both maternal and fetal factors are more frequently seen in pregnancies occurring after assisted fertility treatments, thus increasing the risk of both spontaneous and provider-initiated preterm births. Up to 24% of successful in vitro fertilizations result in multiple pregnancies. The levels of provider-initiated preterm births are increasing in part due to more aggressive policies for caesarean section for poor fetal growth and availability of advanced neonatal care for these tiny babies.

#### IN A NUTSHELL

1. Worldwide annually 2.9 million newborn babies die and 2.6 million babies are stillborn. More than 75% of newborn deaths occur in South Asia and sub-Saharan Africa.
2. In India, 8 million LBW infants are born every year or around 40% of the total of 20 million LBW babies born globally.
3. Newborn infant can be LBW (birthweight <2,500 g), because of suboptimal fetal growth commonly known as IUGR or FGR or due to prematurity (younger than 37 weeks).
4. India accounts for 3.6 million, i.e., 24% of global preterm births and for 303,600 preterm deaths. India tops the list of 10 nations contributing to 60% of the world's premature deliveries.
5. Poor maternal nutrition, *too early, too frequent, and too many pregnancies* are the principle risk factors for LBW. Women with low income, prepregnancy weight less than 40–45 kg, height less than 145 cm, insufficient nutrient intake, low weight gain during pregnancy and lack of antenatal care often produce LBW.
6. Low birthweight is the single most important determinant of neonatal morbidities and mortality. Nearly three-fourth of neonatal deaths and half of infant deaths occur amongst LBW infants.
7. Even after the neonatal period, LBW remain vulnerable to malnutrition, recurrent infection, neurodevelopmental disabilities and death as well as variety of adult onset diseases such as obesity, diabetes, hypertension and coronary artery disease.

## Chapter 13.2

# Prematurity and Intrauterine Growth Restriction

Ashok Kumar, Sriparna Basu

Preterm and intrauterine growth retarded neonates share many common problems, but they also have distinct problems within each group. For convenience of the chapter the problems in each of these groups would be dealt with separately.

### PREMATURE NEONATES

Preterm birth is a major cause of morbidity and mortality in newborns and survivors have significant risks of long-term neurodevelopmental sequelae and functional impairments. The care of preterm infants imposes a heavy emotional and financial burden on families, the health-care system and the society. In recent years the incidence of preterm delivery has shown a steady rise globally, mainly due to indicated (or medically induced) preterm delivery, and multifetal pregnancy after artificial reproductive techniques and fertility-inducing drugs. In general, the risks of morbidity and mortality and long-term sequelae are inversely related to gestational age. The care of preterm newborns constitutes a major fraction of workload in any neonatal intensive care unit (NICU) and contributes disproportionately to the cost of care during initial hospitalization and subsequent period. Due to biologic immaturity, preterm infants are also highly vulnerable to iatrogenic complications.

### Complications of Preterm Neonates

Anatomical and physiological immaturity of different organ systems makes the preterm babies prone to different complications. Moreover, the need of various medical or surgical interventions also increases their risks of complications. The immediate and delayed complications of preterm birth are summarized in **Box 1** and discussed individually.

#### BOX 1 Complications of preterm birth

##### Immediate

- Increased mortality
- Perinatal asphyxia
- Hypothermia
- Hypoglycemia
- Fluids and electrolytes imbalance
- Respiratory distress syndrome
- Systemic hypotension
- Poor maintenance of nutrition and growth
- Patent ductus arteriosus
- Hyperbilirubinemia
- Infection
- Apnea of prematurity
- Necrotizing enterocolitis
- Intraventricular hemorrhage.

##### Delayed

- Retinopathy of prematurity
- Bronchopulmonary dysplasia
- Anemia of prematurity
- Metabolic bone disease
- Poor postnatal growth
- Hearing deficits
- Periventricular leukomalacia.

### Delivery Room Resuscitation and Perinatal Asphyxia

Preterm newborns have many handicaps which make transition from intrauterine to extrauterine life more difficult and challenging. The major handicaps include surfactant deficient lungs which makes ventilation difficult, immature brain with reduced capacity for spontaneous and sustained breathing, and inability to maintain normal body temperature in the absence of external heat. The need for delivery room resuscitation is more frequent in preterm newborns than in full-term babies. Great care should be taken to prevent hypothermia. While resuscitating newborns at less than 28 weeks' gestation, delivery room temperature should be at least 26°C and to reduce heat loss, babies should be covered with polyethylene wraps or bags up to the neck at birth without drying before putting under radiant warmer and starting resuscitation. Temperature of baby must be monitored closely when using these techniques in combination because there is a risk of hyperthermia which can potentiate the cerebral injury. In absence of polyethylene wrapping, exothermic mattresses can be used to maintain the temperature of newborn infants weighing less than 1,500 g within the normal range. Administration of supplementary oxygen should be cautiously regulated by blending oxygen and air since preterms are vulnerable to oxidative stress, and oxygen concentration should be guided by pulse oximetry. Measures for early respiratory support like continuous positive airway pressure (CPAP) and surfactant replacement therapy may be needed at birth and should be readily available in delivery room. In extremely premature infants, early endotracheal intubation may be needed for resuscitation. While assessing Apgar score in preterms, it should be remembered that Apgar score may be falsely low in preterm infants because of poor muscle tone and activity and should be interpreted with caution.

### Hypothermia

High body surface to body weight ratio, diminished subcutaneous fat, decreased brown fat reserve, thin nonkeratinized (permeable) skin, decreased glycogen store in liver, and limited metabolic response to thermal stress predispose preterm infants to hypothermia after birth. Hypothermia may result in hypoglycemia, apnea, infection, metabolic acidosis, disseminated intravascular coagulation, and death.

### Hypoglycemia

During pregnancy fetal blood glucose is maintained by the process of facilitated diffusion from the mother to the fetus via the placenta. Sudden cessation of maternal source of glucose along with insufficient glycogen stores in liver, poor gluconeogenesis, stress at birth and poor oral intake often lead to hypoglycemia. Hypoglycemia may be accompanied with hypothermia, apnea, infection, metabolic acidosis. Prolonged hypoglycemia may lead to brain damage. In extremely low birthweight infants, the incidence of hyperglycemia is also high, because of the poor ability of liver to handle glucose, increased secretion of stress hormones and use of drugs like aminophylline, adrenaline, etc.

### Fluids and Electrolytes Imbalance

In preterm infants, a larger proportion of body weight is contributed by water, with proportionally more fluid in the extracellular fluid compartment than the intracellular one. Physiological diuresis at 48–72 hours after birth, insensible water loss from skin and respiratory tract, and inadequate oral intake contribute to 10–15% weight loss after birth. This loss is further aggravated by use of radiant warmers, phototherapy, poor maintenance of temperature and humidity in NICU. On the other hand, excessive fluid administration is associated with opening of ductus arteriosus, pulmonary edema, intraventricular hemorrhage (IVH), bronchopulmonary dysplasia (BPD) and dilutional hyponatremia.

Hypernatremia and hyponatremia are common and are usually secondary to the disturbances of free water relative to total body sodium. Syndrome of inappropriate antidiuretic hormone secretion, secondary to disease conditions, may also lead to hyponatremia. Hyperkalemia secondary to acute kidney injury is also common.

### *Respiratory Distress Syndrome*

Respiratory distress syndrome (RDS) is the disease of immature lungs and occurs as a result of surfactant deficiency leading to atelectasis, ventilation-perfusion mismatch and alveolar hypoventilation causing hypoxemia and hypercarbia. The RDS is the most frequent cause of admission to NICU among preterm newborns. The incidence is inversely proportional to gestational age, about 50% of neonates born at 26–28 weeks develop RDS, whereas incidence drops dramatically after 34 weeks (<5%). Advances in the care of preterm newborns with RDS including antenatal corticosteroids, early surfactant use, and respiratory support (CPAP or mechanical ventilation) have greatly improved the outcome of these infants.

### *Systemic Hypotension*

Systemic hypotension is a very common diagnosis in preterm infants. An immature myocardium, poor peripheral vasoregulation, absolute volume depletion, shunts through fetal channels like ductus and foramen ovale, cytokine release causing vasodilatation, and the impact of positive pressure ventilation on venous return and cardiac output are the factors which contribute to inadequate systemic perfusion. Hypotension with evidence of inadequate tissue perfusion should be treated with fluid bolus and inotropes. The aim is to maintain mean arterial pressure above the gestational age of the infant in weeks. On the other hand, hypotension without any evidence of end organ perfusion abnormality may not warrant any therapeutic intervention (permissive hypotension).

### *Nutrition and Growth*

Initiation and maintenance of growth as expected in intrauterine life is often a challenge. The main contributing factor is inadequate caloric and protein intake along with breakdown of at least 1.2 g/kg/day of endogenous protein. Oral intake is poor because of incoordinated sucking and swallowing and feeding intolerance. Moreover, concern for necrotizing enterocolitis (NEC) and presence of systemic diseases often delays initiation and advancement of enteral feeding. The growth rate also defaults because of systemic diseases and sepsis. Prolonged use of parenteral nutrition to mimic intrauterine growth rates is also not free from complications and may result in hyperammonemia, cholestasis, sepsis and elevated triglyceride levels.

Extrauterine growth restriction, defined as growth rates less than or equal to 10th percentile of intrauterine growth expectation as per the postmenstrual age at the time of discharge from the hospital, is very common in neonates with birthweight less than 1,500 g. A recent study has estimated the incidence of extrauterine growth restriction to be 28%, 34%, and 16% for weight, length, and head circumference, respectively and for each growth parameter, the incidence increased with decreasing gestational age and birthweight.

### *Patent Ductus Arteriosus*

The ductus arteriosus is normally patent during fetal life and though functional closure of the ductus occurs within few hours after birth, anatomic closure needs several weeks to be complete. In preterm neonates, the ductus may remain patent because of immaturity of smooth muscles or may reopen secondary to disease conditions, like perinatal asphyxia, RDS, volume overload, methylxanthine therapy, etc. The incidence of patent ductus arteriosus (PDA) is

approximately 20% in infants more than 32 weeks and about 60% in less than 28 weeks. Availability of point-of-care echocardiography in the NICU has greatly improved the care of these infants and also avoided the unnecessary treatment of hemodynamically insignificant PDA.

### *Hyperbilirubinemia*

Most of the preterm infants develop significant hyperbilirubinemia requiring treatment. Increased red blood cell destruction, immature liver enzymes causing impaired conjugation and elimination of bilirubin, inadequate oral intake and reduced bowel motility with increased enterohepatic circulation lead to hyperbilirubinemia. Immaturity of blood-brain barrier (BBB) also makes the preterm infants prone for hyperbilirubinemia-induced complications like acute bilirubin encephalopathy, deafness, and kernicterus.

### *Infection*

Risks of infection are increased because of immunologic immaturity, use of different invasive procedures, such as, endotracheal tube, intravascular catheters, central venous lines, frequent handling, breach in mucosal and skin barriers, total parenteral nutrition, lack of breastfeeding, and prolonged stay in NICU. Indiscriminate use of broad spectrum antibiotics in NICU is associated with antibiotic resistant bacteria and fungal sepsis.

### *Apnea of Prematurity*

Apnea of prematurity, defined as cessation of breathing for more than 20s or apnea for less than 20s and accompanied by bradycardia or oxygen desaturation, is commonly seen in preterm infants. The incidence is inversely proportional to the gestational age. Approximately 70% of neonates born before 34 weeks of gestation have clinically significant apnea at least once during first 7 days of life and 50% or more of neonates weighing less than 1,500 g at birth need management with pharmacologic intervention or ventilatory support. Immaturity of the central respiratory center, vulnerability of the brainstem respiratory centers and peripheral chemo and mechanoreceptors to inhibitory mechanisms and mechanical obstruction due to poor muscle tone are the likely explanations for apneic episodes in preterm infants.

### *Necrotizing Enterocolitis*

Necrotizing enterocolitis is the most common gastrointestinal surgical emergency in preterm neonates. It usually occurs after a few days of birth and is characterized by inflammatory damage to the intestinal tract, ranging from mucosal injury to full-thickness necrosis and perforation. The NEC affects extremely preterm neonates with mortality or long-term complication rate above 50% or more depending on severity.

### *Periventricular-intraventricular Hemorrhage*

Periventricular-intraventricular hemorrhage (PVH-IVH) affecting the fragile capillary network of subependymal germinal matrix, is a significant cause of morbidity and mortality in preterm infants. Poor cerebral autoregulation and abrupt alterations in cerebral blood flow and pressure are the main causes of hemorrhage. PVH-IVH is often associated with long-term complications like posthemorrhagic hydrocephalus, neurological deficits, cerebral palsy, developmental delay, and seizures. Since PVH-IVH begins without obvious clinical signs, routine screening and serial cranial ultrasonography are necessary in sick preterm neonates for early diagnosis and management.

### *Retinopathy of Prematurity*

Retinopathy of prematurity (ROP) is a serious vasoproliferative disorder of immature retina which affects the tiniest and sick

premature infants and often leads to severe visual impairment or blindness. Approximately 50–70% of infants with birthweight less than 1,250 g at birth are affected by ROP. Prolonged exposure to supplemental oxygen, mechanical ventilation, PDA, intraventricular hemorrhage and shock are the common risk factors for ROP. Since there are no specific symptoms in neonatal period, routine screening should be done by 4 weeks of age in all infants with birthweight less than 1,500 g or gestational age of 32 weeks or less and selected larger infants with a birthweight of 1,500–2,000 g with an unstable clinical course.

### **Bronchopulmonary Dysplasia or Chronic Lung Disease**

Bronchopulmonary dysplasia or chronic lung disease, defined as the need for supplemental oxygen or ventilatory support at a postmenstrual age of 36 weeks or oxygen dependence after 28 days of life, is a major morbidity of preterm birth. Exposure to oxygen, barotrauma and volutrauma of mechanical ventilation, inflammatory agents, infection, vitamin A deficiency, etc., may lead to BPD in preterm neonates. A distinction has been made between old BPD and new BPD. Old BPD occurred in past in more mature preterm infants before the advent of antenatal steroids and surfactant. There was severe lung injury, characterized by prominent fibrosis, cystic changes, and inhomogeneous aeration of lungs. On the other hand, new BPD is observed in extremely preterm newborns who are exposed to antenatal steroids and receive surfactant replacement therapy. There is minimal fibrosis, more homogenous aeration of lungs, and histologically there is arrest of alveolarization. The developing pulmonary microvasculature can also be injured leading to pulmonary hypertension.

### **Anemia**

Anemia is commonly observed in preterm infants at 4–8 weeks of age. Contributing factors include frequent blood sampling, lower RBC mass at birth and shortened RBC survival, vitamin E deficiency, and rapid catch-up growth. Infant may manifest with poor growth, feeding problems, tachypnea and tachycardia, and pallor. Packed RBC transfusion is indicated in a symptomatic baby, or asymptomatic baby with hemoglobin below 7 g/dL.

### **Metabolic Bone Disease**

Metabolic bone disease is a common disease of preterm infants which generally manifests at 2–3 months of age and is characterized by a reduction in bone mineral content. It may occur in up to 55% of infants born with a birthweight less than 1,000 g and 23% of infants weighing less than 1,500 g at birth. The etiology is multifactorial and includes loss of intrauterine supply of minerals affecting bone mineralization, inadequate intake of calcium, phosphorus and vitamin D, total parenteral nutrition and prolonged immobilization. Since the disease can remain clinically silent for long time routine screening is recommended at 6–8 weeks of age. Low serum levels of phosphorus and high levels of alkaline phosphatase are suggestive. X-ray of long bones is not helpful because radiological changes become apparent only after considerable loss of bone mineral content (> 40%).

### **Hearing Deficits**

Hearing deficits are common in hospitalized premature infants due to immaturity of cochlea, exposure to hyperbilirubinemia, hypotension, ototoxic drugs like aminoglycosides, furosemide and infection and meningitis.

### **Periventricular Leukomalacia**

Periventricular leukomalacia (PVL) is the most common ischemic brain injury in preterm infants affecting the periventricular

region adjacent to the lateral ventricles. Neuropathologically, the lesion often extends beyond the periventricular area to involve the cerebral white matter diffusely. Therefore, the term white matter injury has been proposed to describe this disease entity. Developmental vulnerability of premature brain, hypoxia-ischemia, infection, and inflammation are believed to play central role in the pathogenesis of PVL. The PVL is characteristically a silent lesion in the neonatal period and manifests few months later when spasticity of legs is noticed. The diagnostic hallmarks of PVL are periventricular echodensities or cysts detected by cranial ultrasonography. A significant percentage of survivors develop CP, intellectual impairment, or visual disturbances.

### **Long-term Complications**

The long-term sequelae of preterm births are summarized in **Box 2**. Preterm babies are at 3–5 times higher risk of long-term growth impairment and significant long-term morbidity such as cognitive, visual, and learning impairments than children born at term. The increased risk of CP with decreasing gestational age is well documented. 10.8% of infants of gestational age 22–26 weeks and 6.3% of infants of gestational age 27–32 develop moderate to severe CP in western countries. Recent studies also highlight the range and severity of cognitive, sensory, language, visual-perceptual, attention and learning deficits in very preterm children. A recent meta-analysis has shown that mathematics, reading, and spelling are significantly poorer in very preterm infants. Verbal fluency, working memory and cognitive flexibility are significantly poorer in children born very preterm.

## **NEONATES WITH INTRAUTERINE GROWTH RESTRICTION**

Overall, perinatal mortality and subsequent morbidity have been found to be 8–10 times higher in intrauterine growth restriction (IUGR) fetuses compared to their age appropriate counterparts. Term IUGR neonates weighing between 1,500 g and 2,500 g have a 5–30 fold increase in perinatal morbidity and mortality whereas those less than 1,500 g at term have a 70–100 fold increase in poor perinatal outcomes. A 2013 analysis of pooled overall relative risks for mortality and postneonatal mortality in IUGR infants of low-income and middle-income countries like Asia, Africa, and Latin America were 1.83 [95% confidence interval (CI) 1.34–2.50] and 1.90 (1.32–2.73), respectively.

### **BOX 2 Long-term sequelae of preterm birth**

- **Neurodevelopmental impairments (5–10%):** Global developmental delay, cerebral palsy, cognitive impairments, specific learning disorders, dyslexia, attention deficit hyperactivity disorder, behavioral abnormality, increased anxiety and depression
- **Visual impairment secondary to retinopathy of prematurity (25%):** Blindness, high myopia, or hypermetropia
- **Hearing impairment (5–10%)**
- **Chronic lung disease (40%):** Exercise intolerance, need for home oxygen therapy, reduced lung function, increased rates of asthma and recurrent hospital admissions for respiratory tract infections
- **Cardiovascular complications:** Increased blood pressure
- Increased incidence of noncommunicable diseases
- Growth failure in early life
- Accelerated weight gain in adolescence
- Suboptimal physical productivity
- **Impact on family:** Psychosocial, emotional and economic burden, risk of preterm birth in offspring
- **Impact on health-care services:** High cost of care and utilization of health-care resources
- **Impact on society:** Increased disability and burden of disease.

Depending on fetal biometry, IUGR can be classified into two groups, symmetrical and asymmetrical. Approximately 20–30% of IUGR fetuses are symmetrically small, whereas 70–80% display asymmetric growth restriction. Asymmetric IUGR have a lower ponderal index and are at higher risk for perinatal asphyxia and neonatal hypoglycemia. But there may be a great deal of overlap between these two entities.

### Complications of IUGR

Chronic in utero hypoxia in IUGR fetus is associated with a variety of morphological and functional changes to compensate for the reduced oxygenation and hypoxia-mediated fetal tissue damage. At an initial stage, the human fetus tries to adapt to hypoxia by redistribution of blood flow towards brain and myocardium allowing preferential delivery of nutrients and oxygen to the most vital organs. Cerebral vasodilatation leads to a decrease in left ventricular afterload with systemic arterial vasoconstriction of lower body vessels to increase right ventricular afterload. With continued hypoxia, this protective mechanism is overwhelmed by the decline in cardiac output and the emergence of fetal distress. Finally, there is a decline in systolic and diastolic fetal cardiac function, secondary to myocardial ischemia.

Chronic fetal distress with hypoxia is associated with fetal Doppler arterial waveform velocities indicating reduced systemic flow in descending aorta and umbilical artery and normal or increased blood flow in middle cerebral artery. With progression of fetal cardiovascular compromise, abnormal pulsatility indices in the umbilical artery or middle cerebral artery are seen followed by abnormal peak systolic velocity in the middle cerebral artery with absent or reversed diastolic flow in the umbilical artery. In the most serious progression of fetal compromise, there is reversed flow in the ductus venosus or umbilical vein, indicating the need for an urgent delivery. The complications of IUGR neonates are summarized in **Box 3** and discussed individually.

#### BOX 3 Complications of intrauterine growth restriction infants

- Increased mortality
- Perinatal asphyxia
- Hypothermia
- Hypoglycemia
- Meconium aspiration syndrome
- Persistent pulmonary hypertension of newborn
- Poor maintenance of nutrition and growth
- Polycythemia
- Hyperbilirubinemia
- Infection
- Necrotizing enterocolitis
- Pulmonary hemorrhage
- Congenital malformations.

### Perinatal Asphyxia

Perinatal asphyxia is a potential complication of IUGR. There is high risk of fetal death and severe perinatal asphyxia if IUGR is caused by placental insufficiency with compromised placental perfusion, because during each uterine contraction, maternal placental perfusion further slows or stops by compression of the spiral arteries. When placental insufficiency is suspected, fetal heart rate should be monitored during labor. If fetal compromise is detected, rapid delivery, often by cesarean section, is indicated.

### Hypothermia

Intrauterine growth restriction infants are at risk of hypothermia due to a greater body surface area in relation to weight, less subcutaneous and brown fat reserves, less glycogen stores limiting their capacity of nonshivering thermogenesis.

### Hypoglycemia

Hypoglycemia occurs in 12–24% of IUGR infants, which is 7 times higher than appropriate for gestational age (AGA) infants. Severe IUGR and asymmetric IUGR are more commonly affected. Contributing factors include diminished hepatic and skeletal muscle glycogen, reduced alternate energy substrates such as free fatty acids due to the poor adipose tissue deposition, decreased concentration of lactate, hyperinsulinemia or increased sensitivity to insulin or both, decreased glycogenolysis and gluconeogenesis, and deficient counter-regulatory hormones. The risk of hypoglycemia is common during the first 3 days of life, maximum in the first 24 hours.

### Meconium Aspiration Syndrome

Hypoxia resulting from umbilical cord compression or placental insufficiency may cause the fetus to pass meconium into the amniotic fluid before delivery in about 10–15% of births. During delivery, 5% of neonates with meconium-stained amniotic fluid aspirate the meconium. Intrapartum aspiration of meconium may cause inflammatory pneumonitis and mechanical bronchial obstruction, causing respiratory distress, requiring mechanical ventilation, and high mortality.

### Persistent Pulmonary Hypertension of Newborn

Persistent pulmonary hypertension of newborn (PPHN) is commonly seen in IUGR neonates with perinatal asphyxia and MAS. In PPHN, there is persistence of or reversion to pulmonary arteriolar constriction, leading to a severe reduction in pulmonary blood flow and right-to-left shunting. Symptoms and signs include tachypnea, retractions, and severe cyanosis or desaturation unresponsive to O<sub>2</sub>.

### Polycythemia and Hyperviscosity

Intrauterine growth restriction infants are more prone to develop polycythemia, and the reported incidence is 15–17%. It is more common in asymmetric IUGR and after the gestation of 34 weeks. The increased red cell mass is the result of chronic in utero hypoxemia which increases the erythropoietin levels. Polycythemia can also contribute to hypoglycemia, hyperbilirubinemia and NEC in IUGR infants.

### Hyperbilirubinemia

It is common in IUGR neonates because of increase production of bilirubin from break down of red cell mass in polycythemia.

### Poor Immune Function and Sepsis

Intrauterine growth restriction infants have compromised humoral and cellular immunocompetence, including decreased IgG concentration, phagocytic function and lysozymes. Intrauterine infections commonly result in IUGR.

### Necrotizing Enterocolitis

Necrotizing enterocolitis occurs in IUGR infants secondary to hypoxia, poor superior mesenteric arterial blood flow, polycythemia and infection.

### Pulmonary Hemorrhage

Intrauterine growth restriction infants have significantly lower levels of coagulation factors V and VII and platelet counts. Massive pulmonary hemorrhage has been reported as a cause of sudden unexpected death in severe IUGR infants.

### Congenital Malformations

The risk of congenital malformations or genetic abnormalities is increased 2–3 fold in IUGR infants.

## Long-term Complications

### Poor Growth

Majority (90%) of healthy, term IUGR infants have catch-up growth during first 2 years of life, premature IUGRs may take longer to catch up. The recovery is considered complete when the children reach their mid-parental height. 10–15% of IUGR infants remain short statured with height less than 2 SD during childhood and adult life. These children generally have an adequate endogenous growth hormone secretion in response to pharmacological tests. However, they often have low serum insulin-like growth factor-1 (IGF-1) levels and altered physiological growth hormone secretion and may respond to growth hormone supplements.

For pubertal growth spurt, the age of initiation of puberty is normal in most of the cases. However, an earlier or late puberty has been reported. A decrease in pubertal growth has been observed, especially in females with earlier menarche, suggesting gender-dimorphic susceptibilities.

### Metabolic Risks

Intrauterine growth restriction infants are at significantly increased risk of developing hypertension, dyslipidemia, obesity and type 2 diabetes during adulthood. Several hypotheses have been put forward to explain the association between low birthweight and increased metabolic risks. Barker and colleagues proposed the hypothesis of *fetal programming* to explain the developmental origins of adult diseases. Barker's theory postulated that physiologic adaptations that enable a fetus to survive a period of intrauterine nutritional deprivation result in permanent reprogramming of the development of key organs in the body which have pathological consequences in later life.

The fetal cortisol hypothesis postulated that maternal nutrient restriction may act to reprogram the development of the pituitary-adrenal axis, resulting in excess glucocorticoid exposure and adverse health outcomes in later life. Another hypothesis was fetal insulin hypothesis which proposed that genetically determined insulin resistance results in impaired insulin-mediated growth in the fetus, as well as insulin resistance in adult life.

Obesity is also potentiated by alterations in appetite regulation and increased adipogenesis. Leptin, a primary satiety factor which reduces food intake in a normal child, has been shown to be one of the factors influenced by fetal programming. In IUGR fetuses, cord blood leptin levels are decreased. In addition, IUGR individuals may also demonstrate abnormal activation of adipocytes, leading to obesity.

Hypertension occurs by alterations in renal and blood vessel development. Reduced numbers of nephrons are associated with elevations in arterial blood pressure and changes in postnatal renal function. Diabetes is associated with decreased beta cell number and function along with alterations in cellular insulin signaling.

## PROBLEMS OF PRETERM IUGR

Approximately 30–50% of extremely preterm neonates are born as IUGR. These infants have higher mortality rates than their AGA counterparts and are at significant risk for reduced postnatal growth and development as well as acute and chronic morbidities, such as RDS, BPD, hyperglycemia, NEC, sepsis, ROP and IVH. Contrary to the common belief that the intrauterine stress associated with IUGR may enhance lung maturation, an increased incidence of RDS has been reported in preterm IUGR infants. Postulated underlying mechanisms include delayed metabolic adaptation,

systemic inflammatory response due to chronic hypoxia and free oxygen radical mediated injury. Very preterm IUGR infants have developmentally low insulin secretion and plasma insulin levels leading to hyperglycemia. The risk of NEC in premature IUGR infants is also increased secondary to in utero bowel ischemia due to redistribution of blood flow. Preterm IUGR can also be implicated in the genesis of ROP due to intrauterine hypoxia, altered levels of growth factors, and diminished antioxidant capacity. Neutropenia in extremely preterm IUGR infants, which occurs frequently in those born to pre-eclamptic mothers, adds substantially to the risk of sepsis. Some studies have reported an increased incidence of IVH in preterm IUGR infants though no increased risk for PVL has been found.

### IN A NUTSHELL

1. Preterm birth and intrauterine growth restriction (IUGR) are major causes of morbidity and mortality in the neonatal period as well as in later life.
2. The rates of preterm births have risen worldwide in recent years, mainly due to medically induced preterm delivery, and the global incidence stands at 11.1%.
3. The etiology of preterm births and IUGR is multifactorial with numerous maternal, fetal and uteroplacental factors responsible for these conditions.
4. The major immediate complications encountered in preterm newborns are difficult delivery room resuscitation, respiratory distress syndrome, apnea, hypotension, hypothermia, hypoglycemia, necrotizing enterocolitis, intracranial hemorrhage, feeding difficulties, and vulnerability to infections and iatrogenic complications.
5. Late sequelae in preterm newborns include retinopathy of prematurity, bronchopulmonary dysplasia, periventricular leukomalacia, metabolic bone disease, anemia of prematurity, poor growth and neurodevelopmental impairments.
6. Approximately two thirds of IUGR newborns have asymmetrical phenotype manifesting as reduced weight and length with sparing of brain growth.
7. Immediate complications in IUGR newborns include perinatal asphyxia, hypothermia, hypoglycemia, meconium aspiration syndrome, persistent pulmonary hypertension, pulmonary hemorrhage, polycythemia, infections, and poor growth.
8. IUGR infants are also at higher risk of developing lifestyle disorders in later age such as type 2 diabetes mellitus, hypertension, and obesity due to fetal programming as a consequence of nutritional insult during critical periods of fetal development.

## Chapter 13.3

# Feeding of Low Birthweight

Kanya Mukhopadhyay

Providing optimal nutrition to very low birthweight (VLBW) babies is an essential part of preterm newborn care as extrauterine growth retardation (EUGR) remains a major concern for neonatologists. Preterm babies develop significant calorie and protein deficit during first few weeks of life without adequate nutrition which subsequently becomes difficult to compensate and remains a major cause of postnatal growth retardation.

Though the early aggressive nutrition policy has reduced the initial weight loss and birthweight regain earlier but it is still not optimal. Poor postnatal growth is a predictor of abnormal long-term neurodevelopment. Hence there is a need for a comprehensive nutrition policy for VLBW neonates to improve their postnatal growth.

The concerns and risks of feeding preterm babies include gut immaturity, delayed enteral feeding due to sickness, metabolic immaturity, feed intolerance and risk of necrotizing enterocolitis (NEC), and immature feeding reflexes which delay spontaneous breastfeeding.

## GOAL OF GROWTH

A preterm neonate loses weight initially up to 10–15% and regains birthweight by 2–3 weeks though the regain may be delayed in a sick neonate especially with inadequate nutrition. The initial weight loss is presumed to be predominantly extracellular fluid loss but the contribution by protein, glycogen and lipid losses are not known. The gold standard for growth of preterm neonates is considered to match intrauterine growth rate (~15 g/kg/day) however the body composition acquired in utero is different as compared to postnatal accretion of composition. In utero it is predominantly protein and glycogen while fat accretion occurs mainly during third trimester whereas ex utero major source of nutrients are fat and glucose and less protein, hence body composition differs in the fetus and the newborn infant.

## NUTRITIONAL REQUIREMENTS

### Energy Requirements

Preterm infants have higher nutritional requirements than term infants as they would have missed the rapid period of growth and nutrient accretion during third trimester. In addition postnatal sickness adds to catabolism and leads to higher need of calorie. Energy requirements in preterm babies are approx. 110–130 kcal/kg/day (**Table 1**) and 96–120 kcal/kg/day in a term neonate. Preterm babies lose protein (approx. 1 g/kg/day), lipids and glycogen (approx. 2–5 g/kg/day), and incur a significant energy deficit if adequate nutrition is not provided specially in first few days of life. It has been suggested that small for gestational age (SGA) babies probably have a higher energy need than appropriate for gestational age (AGA) neonates, but data is conflicting. The focus should be achieving an optimal lean mass rather than fat mass which happens with excess calorie and without adequate protein intake.

### Protein

Protein intake has a direct linear relationship with weight gain. In utero accretion of protein during second half of gestation is ~2 g/kg/day and postnatal obligatory protein losses are ~1 g/kg/day. Hence to match in utero protein accretion rate, ~3 g/kg/day

protein is required after birth. In the first few days of postnatal life providing 1 g/kg/day will prevent catabolic loss but there will be no positive nitrogen balance. In a growing preterm baby, extra protein is required to compensate for initial losses and weight gain during growth period. Protein to energy ratio (> 3–3.6 g/100 kcal) also must be considered to ensure adequate growth as significant amount of energy is required for synthesis of new tissue. As per ESPGHAN (European Society for Pediatric Gastroenterology, Hepatology And Nutrition) recommendation, ELBW (extremely low birthweight) neonates require 4–4.5 g/kg/day and 3.5–4 g/kg/day is required for babies between 1 kg and 1.8 kg to sustain adequate growth (**Table 2**). Only high calorie intake may match in utero growth rate but leads to more fat growth than lean body mass.

### Lipid

Lipids are required not only as one of the major source of energy but also to provide essential components for cell membrane functions and bioactive eicosanoids. Considering in utero accretion of 3 g/kg/day and postnatal 10–40% loss from fat malabsorption and 15% unavoidable oxidation and for tissue triglyceride deposition, the fat requirement is about 3.8–4.8 g/kg/day. In babies with restricted fluid intake up to 6.6 g/kg/day may be allowed. Long chain polyunsaturated fatty acids (LCPUFA) are essential requirements for preterm infants for visual and neurodevelopment which is mainly acquired transplacentally during the third trimester. Breastmilk contains all the essential fatty acids but infant formulas contain only precursors linoleic acid and linolenic acid and infants need to synthesize docosahexaenoic acid (DHA) and arachidonic acid. A Cochrane review on LCPUFA supplementation in preterm babies did not show any long-term benefit on growth or visual or neurodevelopment.

### Carbohydrate

This is the main source of energy and ~10.5–12 g/kg/day is recommended for a growing preterm baby. A minimum amount of glucose is required to maintain brain and other glucose dependent organs as well as to prevent protein by preventing gluconeogenesis. Initially a glucose infusion rate of 4–8 mg/kg/min is required to maintain euglycemia which can be increased subsequently to a maximum of 11–12 mg/kg/min.

### Calcium and Phosphorus

Calcium absorption depends on calcium and vitamin D intake and retention depends on absorbed phosphorus. Hence with the aim of retention of 60–90 mg/kg/day and absorption rate of 50–60%, an intake of 120–140 mg/kg/day of calcium is required. Adequate calcium intake is required to ensure adequate bone mineralization in preterm infants. Maintaining calcium to phosphate ratio of 2:1 which is present in human milk, an intake of 65–90 mg/kg/day of phosphate is required. Phosphate absorption is quite efficient in those who are fed human milk or preterm formula but also depends on bioavailability of calcium and nitrogen retention.

**Table 1** Energy requirements for growing preterm infants

Parameter	kcal/kg/day
Resting metabolic rate	50
Energy for activity	5
Thermoregulation	10
Total energy expenditure	65
Energy excreted	15
Energy stored	30–50
Recommended total intake	110–130

**Table 2** Recommended nutritional intake for LBW (ESPGHAN, 2010)

Nutrient	Minimum-maximum (per kg/day)
Fluid, mL	135–200
Energy, kcal	110–135
Protein, g	
Birthweight < 1 kg	4–4.5
Birthweight 1–1.8 kg	3.5–4
Lipids, g	4.8–6.6
Carbohydrate, g	11.6–13.2
Sodium, mg	69–115
Calcium, mg	120–140
Phosphate, mg	60–90
Iron, mg	2–3
Zn, mg	1.1–2
Vitamin A, mcg RE, (1 mcg ~3.33 IU)	400–1,000
Vitamin D, IU/day	800–1,000
Vitamin E, mg ( $\alpha$ -tocopherol equivalent)	2.2–11

Abbreviation: ESPGHAN, European Society for Pediatric Gastroenterology, Hepatology and Nutrition.

### Vitamin D

Vitamin D is important for bone mineralization and neuromuscular function and also improves calcium absorption. Preterm babies are born with low vitamin D stores and quite often born to vitamin D deficient mothers. An intake of 800–1,000 IU/day is recommended in preterm infants. Target level of 25 hydroxyvitamin D (25OHD) is 75–80 nmol/L. Metabolic bone disease or osteopenia of prematurity can arise if there is inadequate intake of calcium, phosphate and vitamin D in VLBW babies. This biochemically manifests as low serum phosphate (< 3.5–4 mg/dL) and high alkaline phosphatase (> 800 IU) and calcium may be low or normal. Rapid mineralization in a growing preterm also can cause increase in alkaline phosphatase but this is not associated with low phosphate. Early enteral feeding and adequate supplementation can prevent this condition.

### Vitamin A

Vitamin A is required for various cellular growth and differentiation. It is required for vision, immune system, normal lung growth and respiratory tract epithelial system. Routine supplementation of 400–1,000  $\mu$ g RE is recommended. Preterm infants have low vitamin A and this has been associated with development of chronic lung disease (CLD). A systematic review showed that vitamin A supplementation reduced the risk of developing CLD.

### Iron

Poor neurodevelopmental outcome has been reported in iron deficiency anemia, however excess dose may be associated with increased risk of infection, poor growth, and disturbed other mineral metabolism. Iron is a pro-oxidant and excess non-protein bound iron produces free radicals which is harmful and can increase the risk of retinopathy of prematurity. A daily intake of 2–3 mg/kg/day is recommended (not more than 5 mg/kg/day) and to be started at 2–6 weeks of age (2–4 weeks in ELBW) and to be continued at least till 1 year of age depending on diet later on. In babies who received multiple blood transfusions, supplementation can be delayed.

## WHEN TO START FEEDING?

All stable preterm babies should be started on feeds as soon as possible after birth preferably with mother's milk. There is no evidence that delaying feeds decreases the risk of NEC whereas risk of delayed feedings are inadequate enzymatic and gut hormone response, delay in establishing full feeds and risk of hepatic dysfunction and sepsis.

### Minimum Enteral Nutrition

Minimum enteral nutrition (MEN) or trophic feeds is a non-nutritive use of a small amount of milk to prime the gut before full feed is provided to a preterm baby. There are several advantages of MEN (**Box 1**). MEN can be initiated in a stable preterm baby irrespective of gestation at the volume of 20–25 mL/kg/day. Breastmilk should be used preferably. MEN is not attempted in severe hemodynamic instability, suspect NEC, paralytic ileus, and any other intestinal pathology. Presence of patent ductus arteriosus (PDA) and presence of umbilical artery catheter are not contraindications for trophic feeds.

### Volume to Start and Rate of Advancement

The ideal volume to start with and the rate of advancement are debatable. The rate of increase depends on weight, gestation, postnatal age, clinical status and tolerance of oral feeds. In most of the babies a maximum volume of 180–200 mL/kg/day can be achieved. There is no evidence that slow advancement prevents NEC but decision should be taken cautiously in ELBW neonates. **Table 3** provides a suggested approach for initiation and hike in stable preterm neonates while transiting from intravascular fluid to enteral feeds.

## METHOD OF FEEDING

Standard method of feeding in less than 32 weeks GA is intermittent orogastric route. There is no evidence that continuous feeding is better than intermittent feeding with regard to time to achieve full feeds, somatic growth and incidence of NEC and babies on continuous feeding needed longer time to achieve full feeds. Babies on nasojejunal feeds are on continuous feeds as jejunum is not capable of handling large volume at a time.

Babies who are less than 32 weeks are started on initially orogastric feeding and then transition to spoon and breastfeeding done. Babies more than 32 weeks can be directly started on spoon feeding. Babies more than 34 weeks can be tried on direct breastfeeding though some babies may need supplemental spoon feeding. Bottle-feeding is strongly discouraged.

### Non-nutritive Sucking (NNS)

All preterm babies who are on orogastric feeding and not on continuous positive airway pressure or ventilator, should be allowed to do non-nutritive sucking on mother's empty breast.

#### BOX 1 Advantages of minimum enteral nutrition (MEN)

- Improves release of gut hormones
- Improves gut motility
- Stimulates cell proliferation, decreases permeability
- Decreases complications associated with gut starvation like villi atrophy, mucosal thinning and bacterial translocation
- Better feed intolerance and earlier full feeds and less days on TPN
- Improved weight gain and reduction in hospital days
- Better calcium and phosphate retention
- Early feeds reduces rate of sepsis and do not increase in NEC.

Abbreviations: TPN, total parenteral nutrition; NEC, necrotizing enterocolitis.

**Table 3** Feeding volume and frequency of feeding for low birthweight babies

Birthweight	Starting volume (mL/kg/day)	Volume increment/day (mL/kg/day)	Max volume (mL/kg/day)	Frequency of feeds
< 1,200 g/GA < 29 weeks	10–20	20	180–200	2 hourly
*1,200–1,500 g/GA 30–32 weeks	20–30	30	180–200	2 hourly
**> 1,500–2,000 g/GA > 32–34 weeks	30	30–40	150–180	2–3 hourly
> 2 kg/> 34 weeks	Full breastfeeds can be tried		Ad lib	2–3 hourly

\*If the baby is well then feed can be started at 50% of total requirement and increased rapidly to full feeds by end of day 1.

\*\*If the baby is well, full feed can be given from the beginning (60 mL/kg/day).

Oromotor stimulation enhances oral feeding skills of preterm infants specially the one with prolonged illness requiring orogastric feeding. There is evidence of earlier attainment of oral feeding, reduction of hospital stay and better breastfeeding rate at discharge in those babies who practiced NNS.

### Feed Intolerance

Feed intolerance is a very common symptom in preterm neonates mostly due to gut pathology, sepsis and electrolyte disturbances. Clinical symptoms of feed intolerance include increased aspirates; vomiting; altered aspirates (bile or blood); abdominal distension (>2 cm from previous or baseline in 6h gap); abdominal wall discoloration (may suggest underlying necrosis); bleeding per rectum; and increase in stool frequency.

## CHOICE OF MILK

### Expressed Breastmilk

Expressed breastmilk remains the choice of feeding in all babies. The benefits of breastmilk are well documented and these are:

- Immunological benefit due to presence of several immunoglobulins, lactoferrin, prebiotics and probiotics and thereby reducing sepsis and NEC. The mortality in ELBW babies with NEC is 35–50% and in VLBW babies 10–30%. Almost 20% VLBW babies die due to sepsis and even the survivors postsepsis are likely to have significant long-term complications like bronchopulmonary dysplasia (BPD) and developmental delay.
- Better bioavailability of nutrients (calcium, iron, fatty acids, etc.) as compared to formula milk.
- Less feed intolerance and early attainment of full feeds (presence of gut hormones, enzymes and growth factors which help in gut growth and thereby establishing full feeds earlier than formula fed babies.
- Possibly better neurodevelopment outcome.
- Improved long-term adult outcome in the form of coronary artery disease, hypertension, type 2 diabetes, etc.

### Donor Expressed Breastmilk

Donor breastmilk through human milk bank is the next best option when there is inadequate lactation of baby's own mother. However the processing causes some loss of immune function and nutritional composition. As pasteurization causes loss of bile salt stimulated lipase, fat absorption is less with donor milk and causes slow growth but still it is associated with long-term advantage. Donor human milk is preferred over preterm formula as risk of gut associated problem is less with human milk. Donor milk should be used only during transition to full enteral feed and all attempts should be made to get baby's own mother's milk. Breastmilk alone or with some formula feed as compared to formula alone is protective against NEC. Donor human milk also probably has similar protective role when compared to formula though poor weight gain is a concern with donor milk.

### Fortified Human Milk

Multicomponent human milk fortifier provides extra calories, proteins, minerals and vitamins. In cases of inadequate growth on full volume milk (180–200 mL/kg/day), especially in babies less than 1,250 g, fortified human milk can be considered to improve weight gain. According to Cochrane systematic review fortification improves short-term weight, length and head circumference (HC) in VLBW babies though no long-term benefit has been documented yet. There is no increased NEC with fortification. Fortifier can be added to breastmilk once the baby reaches 150 mL/kg/day. There no increased risk of NEC with various fortifiers.

### Preterm Formula

In absence of donor breastmilk or inadequate breastmilk, preterm formula is the next choice of feeding in growing preterm infants. They provide nearly adequate calorie, protein, vitamins and minerals if fed in full volume. They contain protein which is predominantly whey based rather than casein based which is more digestible, contains a carbohydrate mixture of 40–50% lactose and 50–60% glucose polymers to compensate for relative lactase deficiency in preterm babies. The fat content is a mixture of 50% medium chain triglycerides (MCT) to compensate for limited pancreatic lipase and bile salt pool which are required for fat absorption and rest 50% is long chain triglycerides which supplies essential fatty acids. In short-term it improves weight gain though no long-term benefit is proven. However risk of NEC is 6–10 times more than those fed exclusive breastmilk and 3.5 times more who are fed combined breastmilk and formula.

**Table 4** provides a comparison of various nutrients in human milk, fortified human milk, preterm formula and when fed at the rate of 150 mL/kg/day.

### Animal Milk

Though animal milk is used very frequently in our country after discharge, there is no study on their impact on growth and neurodevelopment. All components are not equally suitable in growing preterm infants. **Table 5** provides a comparison of various components in animal milk.

## WHEN TO START SUPPLEMENTS?

Babies who are not on fortifier or preterm milk should receive multivitamins, calcium, phosphate and vitamin D supplements as per recommended doses. Supplements can be started after the baby tolerates a volume of 150 mL/kg/day. Fortification can also be initiated at this stage. Iron can be started at the age of 2–4 weeks. Term formula and other animal milk are not suitable for growing preterm babies due to either lack of or excess of certain components as given below. Term human milk fed at the rate of 200 mL/kg/day may meet calorie requirements but still falls short of protein requirements. There is no role of prelacteal feeding in the form of water or dextrose as it has a negative impact on breastfeeding.

**Table 4** Macronutrient and mineral composition of preterm milk, fortified milk and preterm formula per 100 mL and @ 150 mL/kg/day

Nutrients	<sup>#</sup> Recommended intake (per kg/day)	<sup>§</sup> Preterm milk (per 100 mL)	Preterm milk fed @ 150 mL/kg/day	Fortified preterm milk* (per 100 mL)	Fortified preterm milk fed @ 150 mL/kg/day	Preterm formula** (approx) (per 100 mL)	Preterm formula fed @ 150 mL/kg/day
Energy (kcal)	110–135	69	103	82	123	80	120

Carbohydrate (g)	7.1	7.5	4.4	5.1
Calcium (mg)	33	62	120	216
Phosphorus (mg)	15	47	90	—
Iron (mg)	0.03	0.8	0.2	0.2
Vitamin A (IU)	250	200	—	—
Vitamin D (IU)	2.2	40	—	—
Sodium (mEq)	0.8	1.3	—	—

## HOW LONG TO CONTINUE SUPPLEMENTS?

Multivitamins are continued at least till 6 months of life and calcium supplements are given till at least 40 weeks postconceptional age in larger preterm neonates. In small preterm babies who could not be started on adequate calcium or phosphate early, supplements are continued for a longer time along with monitoring of metabolic parameters. Vitamin D is initially given at a dose of 800–1,000 IU which can be reduced subsequently. Iron is continued at least till the age of 1 year and to be stopped depending on adequacy of complementary feeding.

## How Long to Continue Fortification or Preterm Formula?

Fortification should be continued till the baby reaches at least 2.5–3 kg or able to take breastfeeds directly. Preterm formula should

also be continued for the similar duration. Once the babies are off fortification or changed over to term formula or other types of milk, supplements to be provided.

## FEEDING IN SPECIAL SITUATIONS

### Absent/Reversed End Diastolic Flow (AEDF/REDF)

The fetuses who had AEDF or REDF are frequently growth retarded and have less blood flow to gut in order to maintain flow in more vital organs like brain. Hence these babies are more likely to develop feed intolerance and NEC. There is significant controversy regarding initiation and advancement of feeding in these babies. The recent evidence shows that early initiation of feeding by day 2 as compared to day 6 resulted in no higher incidence of NEC. In this study the babies who were less than 29 weeks gestation took significantly longer time to reach full feeds and incidence of NEC was 3 times than babies more than 29 weeks gestation. Use of breastmilk was associated with decreased risk of NEC in these babies. In these cases feeding can be initiated within first 24 hours and may be within 4–6 hours of birth if abdomen is clinically ready for feeds namely:

- No distension or redness
- No altered or increased aspirate
- Passed meconium or bowel sound appeared
- No other contraindication

Feeding should preferably with expressed breastmilk or donor human milk.

### Bronchopulmonary Dysplasia

Babies with bronchopulmonary dysplasia (BPD) require higher energy, 130–150 kcal/kg/day. Though there is no strong evidence of fluid restriction in BPD, as a matter of practice they receive restricted fluid 150–160 mL/kg/day but they should be provided

calorie rich food (fortified or preterm formula) so that energy expenditure along with growth can be taken care. Restriction of fluid may decrease oxygen consumption and improve lung function.

### Patent Ductus Arteriosus

Babies with significant patent ductus arteriosus (PDA) who failed medical therapy and show signs of congestive cardiac failure, need fluid restriction till ligation of the duct can be conducted; though there is no strong evidence whether fluid restriction helps or not.

### GROWTH MONITORING

Growth must be monitored in all preterm babies till discharge and subsequently during follow-up. In the initial phase baby is weighed daily but subsequently during growing period it can be done on alternate days. Length and HC are measured weekly. There are various growth charts intrauterine as well as postnatal growth charts which can be used during hospital stay and till 40 weeks corrected age and after 40 weeks WHO growth charts can be used.

Desired gain till 40 weeks corrected age—for weight 15 g/kg/day, length 0.7–1 cm/week, HC 0.7–1 cm/week. After 40 weeks till about 3 months, weight gain of 20–30 g/day, length and HC 0.5 cm/week are desirable. Inadequate growth is indicated by reduction in growth velocity or failure to gain adequate weight or loss of weight. In a growing baby, weekly serum sodium, calcium, phosphate and alkaline phosphatase should be done till discharge and then monthly till 40 weeks corrected age.

*Failure to thrive* If a growing baby fails to gain weight, following causes should be looked at: adequacy of calorie and protein intake; anemia; cold stress; chronic illness like BPD, postsurgical conditions; fungal infection; urinary tract infection; fluid restricted conditions with inadequate calorie intake in BPD and PDA; and late hyponatremia of prematurity.

*Early aggressive nutrition and outcome* Early aggressive nutrition is aimed at providing high energy and protein supplements as soon as possible after birth in order to prevent significant weight loss. In a preterm baby, especially in ELBW babies, it is not possible to provide required nutrition orally and quickly. Hence to bridge the gap, total parenteral nutrition (TPN) to be provided in the initial days till full enteral nutrition can be established. Early parenteral high protein intake has not been associated with any significant side effects though adequate calories (~3.3 g/100 kcal) also need to be provided along with for growth. Enteral nutrition must be started as soon as the baby is hemodynamically stable at 20 mL/kg/day and in bigger preterms at 30 mL/kg/day with human milk. Feeds can be increased depending on tolerance and TPN needs to be continued till at least 2/3rd of feed volume is achieved.

Early aggressive nutrition policy decreases extra-uterine growth retardation. A comparison of cohort before and after implementation of aggressive feeding protocol showed babies regained birthweight earlier, reached full feeds earlier, discharged home earlier and discharge Z score improved significantly in new feeding protocol. Another study showed that every 10 kcal/kg intake improves mental developmental index by 4.2 points and extra protein intake of 1 g/kg improves MDI 8.4 points at 18 months corrected age.

### Prebiotics and Probiotics

Probiotics are good bacteria and used to colonize premature gut and prebiotics are their substrates. There have been several randomized controlled trials and meta-analysis on use of probiotics and reduction in sepsis and mortality in VLBW infants. However, the settings in which these studies have been conducted

are different from our country. There is also no consensus on best combination or dosages. It is also unknown about their long term immunological effects and rarely infection by probiotic agents has been reported. Hence before recommending routine use of probiotics in our country, some country specific trials are required and long term safety needs to be established. Breastmilk contains several probiotics and more than 130 prebiotics and a combination of both exert a favorable effect in the preterm gut. Hence breastmilk is a better option than commercially available prebiotics or probiotics.

### POSTDISCHARGE NUTRITION

Most of the babies are significantly growth retarded at the time of discharge and continue to have poor catch-up growth. Hence the enriched feed should be continued for some more period postdischarge. In absence of a proper postdischarge formula, fortification and/or preterm formula can be continued till at least the baby is 2.5–3 kg. If the baby is completely breastfed, then maximization of breastmilk intake should be ensured with continued supportive care of mother and her lactation. Supplements should be continued. Continuation of kangaroo mother care may help in maintaining longer lactation period.

#### IN A NUTSHELL

1. Preterm babies need early and adequate nutrition.
2. Adequate protein along with adequate calorie required for optimum growth.
3. Early aggressive nutrition improves discharge weight and reduces postnatal weight loss.
4. Poor postnatal growth is associated with abnormal neurodevelopment which can be improved with early aggressive nutrition.
5. Breastmilk remains the choice of feeding along with mineral and vitamin supplements though some ELBW (extremely low birthweight) babies and those in whom fluids are being restricted may need fortification.

## Chapter 13.4

### Long-term Outcome of Low Birthweight

Suman Rao PN, Nikhil Kulkarni

With advanced medical care, low birthweight (LBW) survival has been steadily improving in the past years. The consequence of LBW extends throughout childhood, adolescence and into adulthood. They are not only at risk of higher postneonatal mortality but also are at risk for poor growth, recurrent hospitalizations, neurosensory impairment, cognitive deficits and behavioral problems (**Box 1**). Hence the needs for special multidisciplinary follow-up services to be set-up as an integral extension of a good neonatal intensive care unit.

#### GROWTH

Low birthweight newborns have poor growth in the neonatal period. There is a decline in the Z score from birth to discharge for weight, length and head circumference. This is followed by *catch-up growth*—an accelerated period of growth in LBW. Catch-up growth is usually first noted in the infant's head circumference, followed by the infant's weight and length. This usually occurs during the first 2–3 years of life. The catch-up growth however may not be complete. Lower gestation, LBW, intrauterine growth restriction (IUGR) and severity of neonatal illness are risk factors for poorer catch-up growth. The Z scores remain low in infancy and early childhood. In a follow-up study of very low birthweight (VLBW) infants from AIIMS, Delhi, it was noted that at 18 months, 30.9% were undernourished, 50.9% were stunted, 14.5% were wasted and 25.4% had microcephaly. The extremely low birthweights (ELBW) were significantly more affected.

The catch-up growth continues during childhood and adolescence; however persistence of height disadvantage into adulthood is common. The COHORTS study includes birth

**Figure 1** Pune LBW cohort study: Growth at 18 years by weight for gestational age with Agarwal, et al standards

cohorts from five low income-middle income countries including India. Adults born preterm were 1.11 cm shorter and term small for gestational age (SGA) were 2.35 cm shorter. Growth failure in the first 2 years is most consistently associated with adult stature emphasizing the need for interventions in intrauterine life or infancy. The Pune LBW study is a birth cohort study of LBW less than 2,000 g born between 1987 and 1989. The preterm SGA infants remained shorter and had smaller head circumference as adults (**Fig. 1**). Other studies from South India (Nair et al., Trivandrum and Christian Medical College Vellore birth cohort study) have also found lower growth parameters on follow-up to adolescence and adulthood. Postnatal growth failure is associated with poor cognitive outcomes and academic achievement. This emphasizes the need for growth monitoring.

The data on effect of LBW on pubertal development, sexuality and fertility is still scarce. Children born SGA have an earlier onset of puberty, smaller amplitude of pubertal spurt and a reduced final height. Girls have an advanced menarche. In the Pune LBW study, sexual maturity and menarche was similar in the LBW groups. In a few follow-up studies, ELBW girls have grown up and have given birth. A transgenerational effect of LBW is seen with the offspring of ELBW infants being smaller.

#### NEUROLOGIC OUTCOMES

Preterm and LBW infants are at risk of variety of developmental problems, psychological and intellectual functioning (**Box 2**). Most Indian studies have used the DASII (Developmental Assessment Scale for Indian Infants), and the Indian adaptation of Bayley Scale of Infant Development (BSID) II for assessment. Mukhopadhyay et al. from Chandigarh followed up a cohort of VLBW infants that included a significant number of ELBW infants. The mean mental and motor quotients at 18 months, were 80.4 (±10.7)

#### BOX 1 Long-term outcome of low birthweight (LBW)

##### Growth

##### Neurologic outcomes

###### Neuromotor

- Cerebral palsy
- Transient neurologic abnormalities
- Developmental coordination disorders

###### Cognitive

- Intelligence quotient
- Speech and language
- School and academic achievement

###### Behavior

- ADHD
- Autism spectrum disorders
- Depression
- Self-esteem

##### General health

- Hospitalizations
- Respiratory
- Bone

##### Developmental origin of diseases

- Obesity
- Diabetes mellitus
- Hypertension
- Dyslipidemia.

Abbreviation: ADHD, attention deficit hyperactive disorder.

#### BOX 2 Cognitive abilities affected in preterm LBW IUGR

- General cognitive ability
- Processing speed
- Attention
- Visual and perceptual skills
- Memory and learning
- Language
- Executive function
- Educational outcomes.

Abbreviations: LBW, low birthweight; IUGR, intrauterine growth restriction.

and 77.2 ( $\pm 13.3$ ), respectively. A score of less than 70 was found in 17% (mental DQ) and 25.7% (motor DQ) VLBW babies.

**Correction for prematurity** Neuromotor and developmental assessments are done and compared after correcting for prematurity. This is known as corrected age (adjusted/post-conceptional age).

Corrected age = Chronological age – (40–gestational age) in weeks

The correction is generally applied till 2 years. But it is suggested that the correction be extended till 3 years for less than 32 weeks, till 5 years for less than 28 weeks and till 7 years for less than 24 weeks.

## NEUROMOTOR OUTCOMES

Preterm children have a different trajectory of motor development. Cerebral palsy (CP) is inversely related to birthweight and gestational age. Neonatal problems such as shock, infection, severe illnesses, and lack of antenatal steroids and use of postnatal steroids are associated with motor disorders. The VLBW infants do not completely outgrow their motor problems which persist into school age and adulthood. Even as adults they have poorer fine and gross motor skills. They are slower than peers. Factors affecting neurodevelopment in LBW are summarized in **Table 1**.

### Cerebral Palsy

The commonest type of CP seen in preterm infants is spastic diplegia. Cystic periventricular leukomalacia (PVL) highly predictive of CP in preterms has decreased but diffuse non-cystic central white matter abnormalities referred to as diffuse PVL occurs in 30–50% of very preterm infants. The preterm SGA is at highest risk for CP. Half of all CP in preterm are mild CP. The CP rate

in Mukhopadhyay's study was 3% despite including a large number of ELBW. This lower rate could be due to the higher gestational age of the ELBW babies and high incidence of IUGR. Early sequential neuroassessment in infancy (by methods such as Amiel-Tison, Voita, Infant Neurological International Battery) is mandatory if CP is to be identified and managed. Spasticity at 3–4 months and persistence of primitive reflexes are early signs of CP.

### Transient Neurologic Abnormalities (TNA)

These are more common in preterm babies with incidence from 40% to 80%. TNA refers to the tonal abnormalities seen in LBW infants during infancy, that peaks at about 7 months but the tone normalizes by 1–2 years. They may be associated with learning disabilities in school age. They are probably a result of milder neurological insults like mild PVL. The follow-up should therefore extend at least to school age if not into adulthood.

### Developmental Coordination Disorder

Developmental coordination disorder is defined as impairment in motor performance sufficient to produce functional impairment that cannot be otherwise explained by the child's age, cognitive ability, or neurologic or psychiatric diagnosis. Developmental coordination disorder is found in 31–34% of VLBW and 50% of ELBW infants. In preterm LBW infants without CP, deficits are reported in motor coordination, balance, visuospatial skills, and hand-eye coordination. This results in developmental dyspraxia, clumsiness, hand writing problems.

## COGNITIVE OUTCOMES

Low birthweight is a risk factor for lower intelligence scores. Assessment can be done using tests such as Wechsler Intelligence Scale for Children-IV, Raven's progressive matrices or Stanford-Binet Intelligence Scales. The preterms are 2.5–3.5 times more likely to have memory impairment. The core deficits of working memory, perceptual-organizational skills, processing speed lead to poor performance on executive function and intelligence tests. Though significantly lower most LBW have intelligence quotient (IQ) within normal limits. Studies have shown that the IQ scores reduce 1.5–2.5 points for each week decrease in gestational age. It is the preterm ELBW IUGR neonates who have the poorest cognitive outcomes. It is also important to highlight that even moderate and late preterms have significantly lower scores on BSID.

The debate on the relative effects of *nature versus nurture* continues. Apart from the biologic variables of birthweight and gestational age, maternal education, home environment, two parent family, type of school and socioeconomic status strongly influence cognitive outcomes. High-risk infants in good environment have the potential for recovery of cognitive and academic performance with improved age. This forms the basis for early interventional programs.

In the Pune LBW study, the intelligence and academic performance of LBW cohort though within normal limits was significantly lower than controls at 12 years (**Fig. 2**). They also had poor visuomotor perception, motor incompetence, reading and mathematics learning disability. The preterm SGA and VLBW children had the poorest cognitive abilities. This continued into adulthood. Nair et al. found low performance scores on intelligence tests in 51.4% LBW versus 41.7 % normal weight adolescents. 14% of LBW and 19% of ELBW had below average IQ.

**Speech and language** Problems of speech and language are common in LBW. They score poorly on language tests even in the absence of a major disability and independent of socioeconomic status. Screening with only IQ tests may therefore not be enough. This impairment continues to adolescence and adulthood

**Table 1** Factors affecting neurodevelopment in low birthweight (LBW)

	Adverse factors	Protective factors
<i>Antenatal</i>	Lower gestational age Lower birthweight Multiple gestation MCMA TTTS Death of co-twin Chorioamnionitis Intrauterine infection	Higher gestational age Higher birthweight Singleton Female sex Antenatal corticosteroids Antenatal magnesium sulphate
<i>Natal</i>	Asphyxia-ischemia	Prompt and adequate resuscitation
<i>Postnatal</i>	Neurobiologic risk score Hypothermia Bronchopulmonary dysplasia Brain injury—PVL/IVH Severe sepsis Severe ROP Shock Necrotizing enterocolitis Poor postnatal growth Postnatal steroids	Exclusive breastfeeding Kangaroo mother care Early intervention therapy Massage therapy Strict SaO <sub>2</sub> target 90–94% Caffeine Restrictive transfusions Nutrition Zinc supplementation Early iron supplementation Early salt supplementation DHA
<i>Social</i>	Poor care givers IQ Single parent Lower socioeconomic status	Maternal education Two parent family High socioeconomic status Parent based early intervention

**Abbreviations:** MCMA, monochorionic monoamniotic; TTTS, twin-to-twin transfusion syndrome; PVL, periventricular leukomalacia; IVH, intraventricular hemorrhage; ROP, retinopathy of prematurity; DHA, docosahexaenoic acid.

**Figure 2** Pune LBW study. Mean IQ (by Raven's progressive matrices) according to weight for gestation. Normal is between 25th and 75th percentiles.

Abbreviations: SGA, small for gestational age; AGA, appropriate for gestational age; FT, full term; PT, preterm.

Source: Chaudhari S, Otiv M, Khairnar B, et al. Pune low birth weight study—birth to adulthood—cognitive development. *Indian Pediatr.* 2013;50:853-7.

particularly for complex language functions. Early language interventions improve outcome.

**Educational outcomes and academic achievement** LBW are at risk of poor school performance, repeating a grade, not completing school or college education. The LBW may experience major difficulties in executive functioning, mathematics and spelling (7.2–11.4 point decrement). Moderate preterm and late preterm infants too have a 50% and 34% adjusted risk of needing special education services respectively.

**Head circumference** A predictor of neurodevelopment: It is long known that head circumference is a surrogate marker for brain growth. The earlier in gestation the head circumference begins to slow, poorer is the neurodevelopmental outcome. Among SGA infants, symmetrical SGA have poorer head growth compared to asymmetrical SGA infants. Even asymmetrical growth restricted newborns may have abnormal brain development despite the external physical appearance of *brain sparing*. Poor head growth postnatally rather than growth restriction at birth is most associated with poor outcome. Those with catch-up growth fare better neurologically.

## BEHAVIOR

Low birthweight infants are at increased risk for behavioral problems such as attention deficit hyperactive disorder (ADHD) and autism spectrum disorders (ASD). The LBW have inattention rather than hyperactivity as the main feature of ADHD and poor social communication rather than stereotype or repetitive behavior as the predominant feature of ASD. Internalizing problems (withdrawn behavior, symptoms of depression) may also be present. This cluster of ADHD, peer relationship problems and emotional disorders has been termed the *preterm behavior phenotype*. Screening for behavioral problems should start at 2 years. This neurocognitive, neurobehavioral sequelae affects even late preterm infants. A new problem that has emerged is *victimization* of premature infants in school. This is in the form of verbal, psychological and physical abuse. As adults, LBW have higher risk of depression, bipolar affective disorders and non-affective psychosis. On the positive front, LBW have been found to have lower risk taking behavior such as smoking, alcoholism, criminality, high-risk sex behavior and drug abuse. Mukhopadhyay reported a high incidence of behavioral disorders in her cohort of

VLBW infants. Most (84.4%) VLBW and all ELBW had a high score for behavioral problems—stressing the need for monitoring for behavioral problems.

**Self-esteem** It is reassuring to know that generally LBW are satisfied with life as adults and have comparable self-esteem as normal weight controls despite their poor growth and health status. Though the preschool child may have lower quality of life scores; this diminishes over time. There is a definite discrepancy between self-reporting and parents or teachers proxy reporting. This could be due to denial or recalibration of expectations. However some studies such as by Nair et al. found lower self-esteem scores among LBW adolescents.

## NEUROSENSORY OUTCOMES

**Ophthalmologic outcome** Impaired vision in VLBW could be due to sequelae of retinopathy of prematurity (ROP). Blindness due to ROP has reduced from 8% to 10% to less than 2% with introduction of cryo-laser therapies. Visual acuity, contrast sensitivity, strabismus, stereopsis, convergence and visual perception are affected in preterm. Preterm brain injury involving the reticulo-geniculate visual pathways can lead to cerebral visual impairment in the absence of ROP. ELBW have 4 times the risk of abnormal acuity, double the risk of errors of refraction, accommodation and 3–9 fold the risk of retinal detachment in adult life. In one study, 64% of ELBW adults required prescription glasses versus 37% of term controls.

**Audiologic outcomes** LBW have higher incidence of hearing impairment (up to 7%) versus 2% in controls. Auditory processing may also be affected. This leads not only to speech impairment but also poorer intellectual, academic and behavior progress. Hearing loss due to otitis media is also common.

## NEUROIMAGING

One review by Voss and on prognosticating cognitive outcomes describe that early testing is generally unreliable (only 49% correct) for later outcome; with the exception of the most severely and obviously affected children. They suggest that follow-up must be at least up to the age of 6 years to make a reliable cognitive diagnosis.

The prognosis may be better determined by newer modalities of neuroimaging. MRI diffusion tensor imaging, voxel-based morphometry and functional MRI demonstrate microstructural evidence of injury and changes in neural connections and cortical maturation that could predict long-term outcomes. Two major findings are decreased white matter volumes and lower fractional anisotropy in specific regions such as posterior limb of internal capsule. Volumetric MRI of the IUGR infant shows reduced cortical gray matter volume, particularly in the hippocampus. PVL is another common feature. MRI is recommended for preterm at term gestation for prognostication.

## GENERAL HEALTH

Low birthweight are at higher rates of health concerns. There is a gradient effect of poorer health outcomes with decreasing gestational age from term to extreme preterm including general health, hospitalizations and chronic illnesses. The most frequently occurring medical conditions are respiratory illness (asthma and recurrent bronchitis), gastrointestinal illness (gastroenteritis and gastroesophageal reflux), viral fever and epilepsy.

Upper and lower respiratory infections are the most frequent cause for rehospitalizations during infancy and early childhood. Asthma and wheezing are more prevalent later in life. The risk factors for repeated hospitalizations due to respiratory illnesses are decreasing gestational age, bronchopulmonary dysplasia, parental smoking, and living with school age siblings. These hospitalizations reduce from early childhood to adolescence.

Respiratory health in adulthood is inversely related to birthweight. Size at 1 year, is a predictor of mortality from respiratory illness in adulthood. Prematurity is associated with airway obstruction, reduced forced expiratory volume in 1 second (FEV1), low forced expiratory flow (FEF) 25–75% and air trapping. Pulmonary functions correlate with high resolution CT scan.

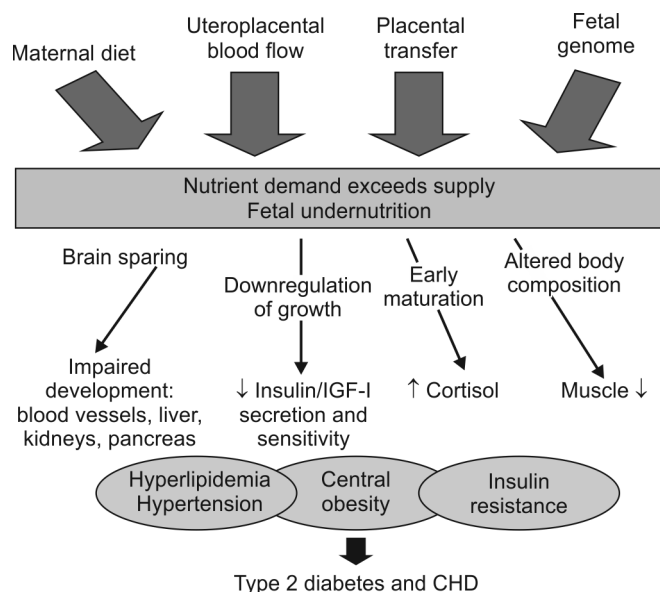

Preterms and IUGR have reduced exercise capacity, and oxygen consumption as young adults even with normal pulmonary function. This may be related to physical fitness. ELBW also have decreased bone mass, osteopenia with risk of pathological fractures.

## THE ADULT FUNCTIONAL OUTCOMES

The LBW does result in residual limitations and challenges extending into adulthood. This affects life achievements, social functioning and socioeconomic status. School completion, higher education, employment is lower in extreme preterm babies, though some studies have shown comparative outcomes. Most ELBW follow-up studies have shown that they are still dependant on their parents, less likely to be married, or be a parent. Female premature babies are at risk for recurrent premature deliveries as adults. Due to functional limitations, former premature adults live a more sedentary life style with less participation in strenuous physical exercise. Despite residual limitations, they report a fairly high quality of life. This phenomenon of discordance between functional limitations and perceived quality of life has been termed *disability paradox*.

## DEVELOPMENT ORIGINS OF HEALTH AND DISEASES

Nutrition deprivation during critical periods of intrauterine life *programs* the fetus to exhibit a *thrifty phenotype*. This programming results in alterations in various fetal organs (**Fig. 3**). Maternal and early postnatal nutrition alters the state of the fetal genome and imprints gene expression by epigenetic mechanisms. The epigenetic alterations explain the transgenerational effects of the thrifty phenotype. Altered appetite regulation results in increased fat deposition. Lipid profile shows elevated cholesterol, triglycerides and low-density lipoprotein. Renal and blood vessel development is altered resulting in hypertension. Alterations in

**Figure 3** Developmental origins of health and disease DOHaD

Abbreviations: DOHaD, developmental origins of health and disease; IGF, insulin-like growth factor; CHD, congenital heart disease.

Source: Adapted from Fall CH. The fetal and early life origins of adult disease. Indian Pediatr. 2003;40:480-502.

cellular insulin signaling and reduced  $\beta$ -cell function results in diabetes. The final result is the full *metabolic syndrome*. Though this is particularly described for the IUGR newborn, it is also seen in preterm LBW neonates with poor nutrition in the first few weeks followed by rapid catch-up growth. Screening blood pressure, glucose tolerance, lipid profiles, should be part of follow-up services for VLBW IUGR children.

In the Pune LBW study at 4 years, LBW had higher insulin-like growth factor-1 and higher blood pressures. After a glucose load, the glucose and insulin concentrations were higher in LBW. However in adults, central obesity or hypertension was not found. Nair et al. found that LBW adolescents at 16 years had higher triglyceride levels and obesity. In the Christian Medical College Vellore cohort, LBW young men had higher blood pressure and a tendency to insulin resistance. The COHORTS study group confirmed that the metabolic syndrome was associated with rapid weight gain in infancy and childhood and an increase in body mass index. Greater weight gains at any age and not just infancy increased the risk of hypertension. Hypertensive adults born preterm have higher systolic and diastolic blood pressure by 4.2 and 3.6 respectively. These differences are considerable given that, at the population level, a 2 mm Hg reduction in diastolic pressure is estimated to result in a 6% reduction in the risk of coronary heart disease and a 15% reduction in risk of cerebrovascular events.

## INTERVENTIONS TO IMPROVE NEURODEVELOPMENTAL OUTCOME

Early interventions to target improvement in neurodevelopment take advantage of the *plasticity* of the newborn brain. Compensatory mechanisms exist in the preterm brain and this plasticity is encouraged by stimulation of neurons. *Cells that fire together wire together*. The mother is the key instrument for all interventional programs. Early interventions include individualized developmentally supportive care [Newborn Individualized Developmental Care and Assessment Program (NIDCAP)], multi-sensory stimulation, physiotherapy, occupational therapy, home-based programs and interventions to improve mother-child interaction. Early interventional programs improve neurodevelopment, but their benefits into late childhood and adulthood are not consistently seen. IQ scores may improve by as much as 10 points. Early intervention programs result in greater school achievements, less grade retention and special education. One of the common and simple comprehensive interventions is kangaroo mother care (KMC).

**Kangaroo mother care** Kangaroo mother care has consistently shown improvement in growth parameters. The benefits of KMC extend beyond the immediate neonatal period into adolescence and adulthood. Bera et al. from Kolkata have documented better growth and DASII scores in KMC group at 1 year corrected age. In another study, KMC had benefits at 10 years in the form of better organized sleep, autonomic functioning, cognition, executive functions, maternal behavior and mother-child reciprocity. As adolescents, transcranial migration stimulation studies were comparable between term controls and LBW receiving KMC and significantly higher than those did not receive KMC.

**Nutritional supplementation** Breastfeeding with mineral supplementation is the *best* food for the LBW. Zinc supplementation in first 2 months may improve linear growth. Docosahexaenoic acid supplementation could improve visual and cognitive outcomes. Iron supplementation improves behavioral outcome. Salt supplementation of 4–5 mmol/day from day 4–14 have better neurodevelopmental outcome. Approximately 10% IUGR do not display catch-up growth. This group has been targeted for growth hormone therapy. Growth hormone may also improve IQ, social acceptance, and feelings of self worth. This is independent of

the weight gain achieved. Lifestyle changes are important from early life to balance developmental origins of health and disease (DOHaD). Blood pressure monitoring should start in early life.

There is a need for development of a dedicated long-term follow-up program up to middle age and beyond to assess the long term impact of LBW. Such a program can be incorporated into already existing newborn follow-up programs like *Rashtriya Bal Swasthya Karyakram*.

### IN A NUTSHELL

1. Catch-up growth in low birthweight (LBW) may not be complete. Lower the gestational age and birthweight, poorer is the catch-up growth.
2. Developmental assessment should be done as per corrected age. Correction for prematurity may have to be continued beyond 2 years in extreme preterm babies.
3. Low birthweight babies are at risk for motor abnormalities ranging from transient tonal abnormalities to cerebral palsy; poorer cognitive outcomes such as lower IQ and poorer academic achievements; behavioral problems such as attention deficit hyperactive disorder (ADHD) and autism spectrum disorders (ASD); and neurosensory problems like retinopathy of prematurity (ROP) and hearing loss.
4. LBW babies continue to be compromised in general health in adulthood as witnessed by recurrent respiratory illness and are also at risk for metabolic syndrome [developmental origins of health and disease (DOHaD)].
5. Kangaroo mother care (KMC), nutritional supplementation and early intervention with good maternal child interaction are known to improve neurodevelopmental outcome of LBW babies.

## Chapter 13.5

### Postmaturity

Reeta Bora, Pranay Phukan

Postmaturity or post-term pregnancy is not an infrequent problem in clinical practice and is associated with increased perinatal and neonatal mortality and morbidity. For proper management to reduce these complications, the condition needs a combined effort of obstetrician and pediatrician.

#### DEFINITION

WHO defines post-term birth as a birth occurring at a gestational age of 42 weeks (294 days) or greater assuming a menstrual cycle of 28 days. Post-term babies who have begun to lose weight but have normal length and head circumference are said to be postmature. In 2013, The American College of Obstetrics and Gynecology's Society of Fetal and Neonatal Medicine has redefined term pregnancy to improve neonatal outcome and expand efforts to prevent non-medically indicated termination of pregnancies before 39 weeks of gestation. A series of more specific labels have been proposed for use. The terminologies used to redefine delivery at term and beyond are:

- *Early term*: Between 37 weeks 0 days to 38 weeks 6 days.
- *Full term*: Between 39 weeks 0 days to 40 weeks 6 days.
- *Late term*: Between 41 weeks 0 days to 41 weeks 6 days
- *Post-term*: Between 42 weeks 0 days and beyond.

#### INCIDENCE

The overall incidence of post-term pregnancy has been reported in western literature to be approximately 3–12% of all pregnancies. In the United States the incidence has been reported as 5.6% whereas in Europe it has been found to be as high as 8.1%. No data could be found published from India mentioning incidence of post-term pregnancy.

The definition of normal human gestation is itself open to discussion. Mean duration of pregnancy may vary among different population and under different conditions. For example gestations ending in summer months may be longer than those ending in winter, pregnancy with male fetus may be longer than with female fetus. Race, ethnicity and country of origin of mother are associated with differences in average duration of pregnancy. It has been mentioned in the literature that perinatal complications seem to increase in some population starting as early as 38 weeks of gestation. However, overall risk of perinatal mortality increases with pregnancy beyond 41 weeks of gestation.

Although last menstrual period (LMP) has been traditionally used to calculate gestational age and expected date of delivery (EDD), it may be inaccurate many a times in women who have had irregular menstrual cycles, who have cycle length other than 28 days, who have been on hormonal birth control pills, women who have inconsistent ovulation times and those who had 1st trimester bleeding. Hence not only LMP but also other important factors needs to be considered while calculating EDD or gestational from LMP, so as not to overestimate incidence of post-term pregnancy. Obstetric ultrasonography (USG) at 1st trimester can improve estimation of gestational age but it is important to understand that there is a margin of error of +3–5 days. Second and third trimester USG are not reliable for assessing gestational age as they have wide margin of error (7–10 days in 2nd trimester and 3 weeks in 3rd trimester.)

The importance of determining by what method a pregnancy is dated cannot be overemphasized because this may have significant

consequences on the neonatal outcome. There are risks to the neonate both if the physician delivers a so-called term pregnancy that is not or observes a so-called term pregnancy that is very post-term.

#### RISK FACTORS

Maternal factors like genetic predisposition, primiparity, prior post-term delivery are risk factors for post-term delivery. Recently maternal obesity (maternal body mass index of more than 29 kg/m<sup>2</sup>) has been mentioned as a risk factor for post-term delivery. Elevated pre-pregnancy weight as well as weight gain during pregnancy, both have been found to increase risk of post-term delivery. Maintaining maternal weight gain in a recommended range can prevent post-term pregnancy.

Placental sulfatase deficiency may be another factor leading to post-term pregnancy. Fetal factors like chromosomal abnormalities, e.g., trisomy 16 and 18, anencephaly, fetal pituitary adrenal axis anomalies have been mentioned as fetal causes of post-term pregnancy but with modern obstetric care these causes are rare (Table 1).

**Table 1** Risk factors associated with post-term pregnancy

Maternal factors	Fetal factors
Genetic predisposition	Trisomy 16, 18
Primipara mother	Anencephaly
Prior post-term delivery	Fetal pituitary adrenal axis anomaly
Maternal obesity	Seckel syndrome (bird headed dwarfism)
Placental sulfatase deficiency	

#### PERINATAL OUTCOME

Several population based studies have shown that the risk for fetal death is higher in post-term pregnancy than those with term gestation. The risk has been found to be increased by a factor of 1.5 in nulliparous women as compared to multiparous women. This risk has been calculated traditionally as rate of fetal loss per 1000 livebirths, however this risk may increase further if calculated as proportion of ongoing pregnancies. The stillbirth rate has been cited in a population based study to be, 1.27/1000 ongoing pregnancies at 41 weeks, 1.55/1000 at 42 weeks of gestational age and 2.12/1000 ongoing pregnancies at 43 weeks of gestational age.

It is well established that post-term pregnancy is associated with labor dystocia, severe perineal injury in mother and is also associated with increased incidence of cesarean delivery. The incidence of intrauterine fetal demise plus neonatal deaths, meconium aspiration, infectious morbidity, birth trauma, low Apgar score and low umbilical cord pH level increases in post-term pregnancy as compared to term. Occasionally macrosomia (defined as birthweight more than 4,500 g) and associated birth injury is also seen to be associated with post-term pregnancy. The low Apgar score in post-term pregnancy has been found to be related to postmaturity and meconium aspiration syndrome. At 42 weeks the stillbirth rate and early neonatal death rate have been found to be twice as that of at 40 weeks and the risk trebles at 43 weeks. Due to the maternal and neonatal morbidity associated with post-term pregnancy, the American Academy of Obstetrics and Gynecology recommends initiation of antenatal surveillance between 41 weeks and 42 weeks of gestation. Induction may be indicated after discussion of risks and benefit of induction with mother.

The risk for fetal demise has been found to be higher in recent studies compared to those mentioned in older studies, the reason being many pregnancies which were termed post-term in older studies were probably term pregnancies as dating was done traditionally by using LMP rather than using 1st trimester USG.

The perinatal morbidity and mortality in post-term pregnancy may be related to the slow deterioration of placental blood flow and function and progressive increase in size of the fetus. These changes as occur over a period of time after term, the risk of perinatal complications might be expected to increase with advancing gestational age in a continuous rather than threshold fashion. Studies have shown that the risk of maternal and neonatal complications increase as pregnancy progresses beyond 40 weeks of gestation (**Fig. 1**).

**Figure 1** Perinatal risk index and perinatal mortality rate for birth between 37 weeks and 43 weeks

Source: Adapted from Am J Obstet Gynecol Vol 184, 2001.

## POSTMATURITY SYNDROME

Ballantyne (1902) first reported this syndrome and Clifford (1954) described it as a recognizable clinical syndrome. 20% of post-term neonates have a risk for postmaturity syndrome. These post-term neonates have begun to lose weight due to poor placental blood supply leading to progressive reduction of oxygen supply, but have normal length and head circumference. The outcome of postmaturity includes oligohydramnios, cord compression, fetal distress and meconium aspiration. Many authors prefer to use the term *dysmaturity syndrome* for such babies rather than using *postmaturity syndrome* as although in the past the clinical features suggestive of this syndrome was attributed to prolonged pregnancy and was thought to be seen only in neonates delivered after prolonged pregnancy, recent work has shown that the constellation of signs may be found in neonates of any gestation with placental insufficiency (**Fig. 2**).

**Classification** Postmaturity syndrome is further classified traditionally into three stages:

**Stage I** includes those postmature infants who have dry crackled skin, loose and wrinkled skin with malnourished appearance, decreased subcutaneous tissue with alert eyes.

**Stage II** includes infants with all features suggestive of stage I with meconium staining of amniotic fluid and perinatal depression.

**Stage III** babies have all features of stage I and II and meconium staining of skin, nails suggestive of long standing meconium staining of amniotic fluid. Neonates with stage III condition have high risk for fetal, intrapartum and neonatal death.

Recent evidence suggests that the risk of meconium staining, asphyxia and mortality increases beyond 41 weeks and 42 weeks by itself is not a threshold below which risk is low. There is also evidence that nulliparous women have a higher risk of perinatal mortality if pregnancy is postterm compared to multiparous women. Post-term neonates with postmaturity syndrome are

**Figure 2** Neonate with postmaturity syndrome

also known to be at risk of persistent pulmonary hypertension, neonatal seizures, metabolic derangements like hypoglycemia and hypocalcemia.

## LONG-TERM OUTCOME

Postmaturity syndrome has also been found to be associated with long-term neurological and developmental consequences including lower social quotient at 12 months of age and lower Bayley mental developmental score at 8 months of age. Mortality in 1st year of life seems to be increased in this group of babies as compared to those delivered at term. Behavioral and emotional abnormalities, specially attention deficit or hyperactive disorder have also been reported in infants who were delivered post-term. In one study in long-term post-term boys were found to have accelerated weight gain during adolescence leading to obesity. It has been proposed that prolonged gestation may lead to suboptimal fetal environment through inadequate fetal nutrition and physiological stress, resulting in long-term abnormal postnatal body composition. **Box 1** summarizes the outcomes of post-term births.

### BOX 1 Outcomes associated with post-term delivery

1. Increased perinatal mortality
2. Perinatal morbidity
  - Low Apgar score and perinatal asphyxia
  - Meconium aspiration syndrome
  - Increased NICU admission
  - Persistent pulmonary hypertension
  - Hypoglycemia, polycythemia
3. Long-term morbidity
  - Delayed and abnormal development
  - Decreased social quotient
  - Increased rate of hospitalization in 1st year of life
  - Childhood obesity.

Abbreviation: NICU, neonatal intensive care unit.

**Maternal risk** Higher incidences of perineal injury (third and fourth degree perineal laceration), cesarean section, hemorrhage and infection are seen in mothers with post-term pregnancy compared to those with term pregnancy.

## MANAGEMENT

**Antenatal** Gestational age should be assessed carefully including 1st trimester USG data. Antenatal assessment should be done by

antenatal fetal monitoring from 41 weeks onwards by twice weekly. The first decision that must be made when managing a post-term pregnancy is whether to deliver or to wait expectantly. A non-reassuring fetal surveillance result, oligohydramnios, fetal growth restriction, or certain maternal diseases like pregnancy induced hypertension makes the decision for delivery straightforward. However, frequently several options can be considered when determining a course of action in the low-risk pregnancy. The certainty of gestational age, cervical examination findings, estimated fetal weight, patient preference, and past obstetric history must all be considered when mapping a course of action. Elective induction of labor has been used increasingly for management of such pregnancies. Recent systematic reviews and meta-analysis of randomized controlled trials comparing routine induction with expectant management of mothers with post-term pregnancy concluded that labor induction may reduce perinatal and neonatal mortality but without increasing risk of cesarean delivery.

**Intrapartum** As perinatal asphyxia and meconium aspiration are common in such pregnancies, the delivery of the fetus should be attended by a person expert in neonatal resuscitation including intubation. Delivery of such pregnancies should ideally be conducted in a health set-up with facility for managing neonates with complications like meconium aspiration syndrome, persistent pulmonary hypertension, etc. Procedures like amnioinfusion, suction of oropharynx at perineum, etc. have not been found to be effective in reducing meconium aspiration syndrome contrary to popular belief. Undiagnosed fetal chromosomal abnormality remains a probability in such pregnancies, hence neonates should be closely examined after delivery for such abnormality.

**Postpartum management** This includes close monitoring of the neonate for conditions like persistent pulmonary hypertension, hypoglycemia, hypocalcemia, neonatal seizure, neonatal encephalopathy and polycythemia to which these babies are prone to. If such conditions are detected they should be managed

accordingly. Meconium aspiration and persistent pulmonary hypertension will indicate need for ventilator care. Neonatal seizure may be there in these babies because of neonatal encephalopathy or metabolic derangements like hypoglycemia, hypocalcemia, etc. These conditions if present would indicate need for secondary or tertiary level care for the baby.

### IN A NUTSHELL

1. Post-term delivery with an incidence of 2–5% is not rare and is consistently associated with small risk of rise in perinatal death and neonatal morbidity.
2. Duration of normal human gestation may vary in different population.
3. Careful assessment of duration of gestation is necessary before intervention.
4. Twenty percent of post-term pregnancy may be associated with postmaturity syndrome.
5. Close monitoring of pregnancies after 40 weeks of gestation and careful antepartum, intrapartum management may prevent many of the mortality and morbidities.

## Chapter 13.6

# Large for Gestational Age

Rhishikesh Thakre

Large for gestational age (LGA) is an abnormal growth descriptor used as a diagnostic tool and a prognostic marker. The LGA neonates are defined as having weight for gestation above the 90th percentile on the growth chart. However, it seems the optimal birthweight percentile in defining LGA is 2 standard deviations (> 97th percentile) above the weight for gestation as this identifies neonates at highest risk for perinatal morbidity and mortality. *Macrosomia* is a clinical term used to describe an abnormally large fetus regardless of gestational age (birthweight > 4500 g). The LGA are at high risk for perinatal morbidity and potentially long-term metabolic complications.

## EPIDEMIOLOGY

Large for gestational age affects 1–10% of all pregnancies. There is racial and ethnic variability in the incidence of LGA infants. A steady rise in the prevalence of LGA newborns over a few decades has been noted in many parts of the world including developing countries due to increasing prevalence of diabetes, gestational diabetes, obesity and lifestyle changes.

## ETIOLOGY

Birthweight is influenced by many factors, many of which are known (**Table 1**) and some unknown (idiopathic). The majority of large babies are due to large mothers (constitutional). Excessive fetal growth can occur because of genetic factors or increased supply of nutrients. Maternal body mass index (BMI), diabetes, and weight gain during pregnancy are known to be positively associated with infant size at birth. There are many risk factors which predispose a mother in having large for gestational age birth, however, the extent to which each of these factors influence birthweight is unclear (**Table 2**).

## PATHOPHYSIOLOGY

The growth of the fetus is complex and dependent upon numerous factors like maternal uterine environment, functioning of the

placenta, and availability of nutrients to mother and fetus. One of the commonest causes of LGA is maternal diabetes. Un-controlled maternal diabetes, leads to fetal hyperglycemia stimulating the beta cells of pancreas resulting in fetal hyperinsulinemia. Because insulin is an anabolic hormone the fetal hyperinsulinemia stimulates protein, lipid and glycogen synthesis causing increased fetal body fat, excessive adipose deposition, visceral organ hypertrophy, and acceleration of body mass accretion to cause macrosomia. Macrosomia leads to complications of delivery, such as shoulder dystocia, obstructed labor, perinatal asphyxia and birth injury. Fetal hyperinsulinemia also causes elevated metabolic rate, leading to increased oxygen consumption and fetal hypoxemia predisposing to intrapartum complications (fetal distress, still births), inhibition of the normal maturational effect of cortisol on the lung leading to delayed pulmonary maturation processes required for surfactant production (RDS), and persistence into neonatal life contributes to the propensity to develop neonatal hypoglycemia.

Not all LGA fetuses are due to hyperinsulinemia. Parents of large stature (weight or height), obese mothers and those who gain excessive weight during pregnancy lead to excessive delivery of nutrients to the fetus and contribute to increased fetal growth. Possibility of one of the rare syndromes associated with accelerated fetal growth should be considered, particularly in the presence of one or more fetal structural anomalies (**Table 3**). Limited data suggest that placental epigenetic alterations may contribute to increased fetal growth.

## CLINICAL FEATURES

### Delivery Room

The classical appearance of LGA is large, plethoric baby due to increased body fat in the abdominal and scapular regions (**Fig. 1**). The higher the weight greater is the risk of complications of delivery, such as shoulder dystocia, obstructed labor, perinatal asphyxia and birth injury (e.g. brachial plexus injury (**Fig. 2**) or fractured clavicle or humerus (**Fig. 3**). The rate of birth injury is more in vaginal compared with cesarean deliveries. The extremity may appear swollen, tender with minimal movement because of pain (pseudoparalysis) due to underlying bone fracture. Physical findings of brachial plexus injury are distinctive. Erb's palsy (C5–7) has classical waiters tip hand, i.e., forearm is pronated and the wrist flexed with asymmetrical Moro reflex. Klumpke palsy (C8–T1) affects small muscles of the hand, wrist and finger flexors (claw hand deformity) with absent grasp reflex. Horner syndrome (30% in Klumpke palsy, involves T1), causes ptosis, miosis on affected

**Table 1** Etiology of large for gestational age (LGA) infants

• Constitutional
• Maternal obesity/overweight
• Prepregnancy/pregnancy diabetes
• Hydrops fetalis
• Genetic (Beckwith-Wiedemann syndrome, Simpson-Golabi-Behmel syndrome, Perlman syndrome, Sotos syndrome, Weaver syndrome, Costello syndrome)

**Table 2** Risk factors for LGA infants

• Multiparity
• Advanced maternal age (≥30 years)
• Post-term pregnancy (≥ two fold risk)
• Previous history of large baby
• Excessive weight gain in pregnancy (≥20 kg)
• Maternal birthweight > 4000 g
• Male sex

**Figure 1** Large for gestational age infant

**Table 3** Genetic syndromes with large for gestational age (LGA) neonates

Condition	Characteristic
Beckwith-Wiedemann syndrome (BWS) (AD)	Macroglossia, linear fissure in ear lobule, visceromegaly, neonatal hypoglycemia, hemihypertrophy, cryptorchidism
Perlman syndrome (AD)	Hypotonia, mental retardation, depressed nasal bridge, anteverted upper lip, mild micrognathia, nephromegaly, bilateral cortical hamartomas, increased risk for Wilms tumor
Sotos syndrome—Cerebral gigantism (Sporadic)	Macrocephaly, dolichocephaly, ventriculomegaly, downslanting palpebral fissures, hypertelorism, prognathism, high narrow palate, premature eruption of teeth, large hands and feet, kyphoscoliosis, mental deficiency
Weavers syndrome (Sporadic)	Mental retardation, hypertonia, hoarse voice, macrocephaly, round face, ocular hypertelorism, downslanting palpebral fissures, long philtrum, large ears, micrognathia, camptodactyly, thin deep-set nails, prominent fingertip pads
Simpson-Golabi-Behmel syndrome (XLR)	Macrocephaly, coarse facies, macrosomia, hypertelorism, macroglossia, cleft lip, nail hypoplasia, macrostomia, postaxial polydactyly, umbilical/inguinal hernias, visceromegaly, skeletal abnormalities, increased risk for embryonal tumor
Costello syndrome	Coarse facies, loose skin, diffuse hypotonia, joint laxity, sparse fine hair, failure to thrive, increased risk for malignant solid tumors

Abbreviations: AD, autosomal dominant; XLR, X-linked recessive.

**Figure 2** Brachial plexus injury of right hand**Figure 3** Note the fullness of right arm with paucity of movement suggesting underlying fracture humerus due to shoulder dystocia

side. Minor congenital anomalies are more common in LGA than AGA infants. The most common anomalies associated are talipes calcaneovalgus, hip subluxation, hydrocephaly and nonbrown pigmented nevi. Two-thirds of the anomalies in infant of diabetic mother (IDM) involve the cardiovascular or central nervous system. Poor feeding is a major problem; it occurs in almost one-third of infants and is often present in the absence of other problems.

### Neonatal Unit

The most common diagnoses in LGA infants, which account for nursery admission, are respiratory distress syndrome (19%, due to surfactant immaturity in diabetes), transient tachypnea of the newborn infant (16%, due to increased cesarean section delivery), hypoglycemia (9%), and meconium aspiration (9%). Almost half of the IDM need admission to neonatal intensive care unit (NICU). Up to 15% of all LGA infants and 50% of IDM develop hypoglycemia which may be symptomatic (irritability, lethargy, apnea, grunting, respiratory distress, tachypnea) or asymptomatic. The highest risk is between 1–4 hours and unlikely beyond 48 hours of birth. Hence all LGA need monitoring for blood sugar. Unrecognized hypoglycemia can lead to seizures (0.3%), encephalopathy, and brain damage. Initial jitteriness hypotonia followed by increased tone, and seizures are signs and symptoms of brain injury secondary to perinatal asphyxia. Prematurity, increased RBC destruction contribute to development of indirect jaundice. Polycythemia can lead to poor circulation and exacerbate hyperbilirubinemia.

### DIFFERENTIAL DIAGNOSIS

Large for gestational age infants may be due to overweight or obese mothers (constitutional), maternal diabetes, hydrops fetalis or genetic syndromes. The characteristic features of each are in **Tables 3** and **4**. An infant with hydrops has an abnormal accumulation of excess fluid leading to generalized edema with effusions in multiple body cavities.

### Approach to Diagnosis

Identification and evaluation of neonate at risk for LGA should begin during pregnancy, and such neonates should be followed up postnatal. A thorough family and pregnancy history shall help to identify *at risk* mothers and provide appropriate anticipatory care to prevent complications. Fetal well-being is commonly assessed through the use of maternal glucose tolerance testing, nonstress testing, and biophysical profiles. Trend in maternal weight gain

**Table 4** Characteristics of LGA and infant of diabetic mother (IDM)

Features	LGA	IDM
Macrosomia	+	+
Asphyxia	+	+
Birth trauma	+	+
Hypoglycemia	+	+
Hyperbilirubinemia	+	+
RDS, MAS, diaphragmatic palsy, air leak	–	+
Polycythemia	–	+
Congenital anomalies	–	+
Hypocalcemia, hypomagnesemia	–	+
Organomegaly	–	+
Neurologic sequelae	–	+

is monitored. Causative factors for LGA neonates are investigated antenatally. Prenatal management is aimed at determining the ideal time and mode of delivery depending on obstetric factors.

At least one person capable of neonatal resuscitation should be present at the time of birth. In the well infant, routine care should be provided. A rapid assessment is done for presence of any birth injury, congenital malformations, and evidence of macrosomia, hypoglycemia, respiratory distress or genetic syndrome. All babies should have weight, length, and head circumference plotted on the growth chart [e.g. modified Fenton's chart for preterm, WHO (2005) chart for term infants]]. Weight more than the 90th percentile for gestational age confirms the diagnosis of LGA. A focused physical examination from head to toe should be done (**Table 5**).

## MANAGEMENT

### Delivery

For the majority of pregnant women who are not diabetic, a policy of elective cesarean delivery for ultrasonographically diagnosed fetal macrosomia is medically and economically unsound. In pregnancies complicated by diabetes, such a policy appears to be more tenable, although the merits of such an approach are debatable. Most recent studies do not show any advantage to induction before the due date. Early neonatal complications such as asphyxia, birth trauma and hypoglycemia must be anticipated. In absence of any complications, routine care should be provided and baby handed over to the mother for skin-to-skin contact and early breastfeeding.

### Supportive Care

Infant of diabetic mothers with asphyxia, congenital malformations, history of maternal insulin administration, unstable vital parameters and hypoglycemia should be admitted to nursery and should receive supportive care while being evaluated for hypoglycemia, hypocalcemia, polycythemia, and hyperbilirubinemia. All LGA newborns are nursed in thermoneutral environment. Vital parameters are continuously monitored using pulse oximetry. State of well-being, sensorium, tone, cry and activity and perfusion is assessed periodically. Every attempt is made to ensure early supervised feeding. Gavage feeding may be started if there is poor oral-motor coordination. Those unable to tolerate enteral feeding are initiated on IV fluids.

### Glucose Control

Glucose sampling is usually accomplished during the first 2 hours after birth and monitored as per unit policy. Glucose value less than 45 mg% identifies hypoglycemia. Asymptomatic LGA with blood glucose 25–45 mg% are offered additional supervised oral feeds and reassessed. Sick infants, blood glucose less than 25 mg%, inability to tolerate enteral feeding, or those who remain hypoglycemic

**Table 5** Evaluation of LGA infants

Appearance	Plump, well-nourished, proportionately large head and body
Activity	Irritable (asphyxia, fracture, pain), drowsy (asphyxia, intracranial hemorrhage, hypoglycemia), lethargy (hypoglycemia, spinal cord injury), jitteriness, poor feeding (hypoglycemia, trauma)
Cry	High-pitched cry, inspiratory stridor, dysphonia (difficulty crying), or dysphagia (difficulty swallowing) may indicate unilateral or bilateral vocal cord paralysis
Head	Small fontanel (overlapping sutures), large fontanel, metopic suture (Beckwith-Wiedemann syndrome (BWS), caput succedaneum, cephalhematoma, subgaleal hemorrhage)
Face	Bruises, abrasions, nasolabial fold-drooping mouth-open eye (facial nerve palsy), hairy pinna (IDM), pinna abnormalities—macroglossia (BWS)
Skin	Increased subcutaneous fat, increased muscle mass, meconium staining (MAS), jaundice (increased bilirubin production due to macrosomia, polycythemia, adrenal hemorrhage), pallor and poor perfusion (shoulder dystocia), bruises, abrasions, plethora, nonbrown pigmented nevi
Limbs/bones	Movements, symmetry, swelling, tenderness, crepitus (fracture, dislocation, trauma), Talipes, DDH, Erb palsy, Klumpke palsy
Respiration	High respiratory rate, work of breathing (RDS, MAS, asphyxia, TTNB, phrenic nerve palsy, CHD)
Abdomen	Mass, organomegaly (adrenal hemorrhage or subcapsular hematoma of liver, BWS), umbilical hernias, omphalocele and diastasis recti (BWS), single umbilical artery (genitourinary-cardiac anomalies), Non-passage of meconium (hypoplastic left colon)
Heart	Murmur, abnormal pulses, cyanosis (CHD, PPHN)
Tone	Hypotonia-apnea-areflexia (spinal cord injury),
Reflexes	Moros for symmetry (fracture clavicle or humerus, brachial plexus injury), Suck (facial palsy), Grasp (absent in Klumpke palsy)
Genitalia	Inguinal hernia, cryptorchidism, clitoromegaly (BWS)

despite full enteral feeds, should receive an intravenous infusion of glucose at an initial rate of 6 mg/kg/min and increasing rapidly if indicated by repeat blood glucose monitoring. The blood glucose is maintained above 45 mg%. 2 cc/kg of 10% glucose bolus followed by glucose infusion is restricted to symptomatic hypoglycemic newborns. Seizures are most commonly due to hypoglycemia and comorbid conditions like sepsis, asphyxia, hypocalcemia, electrolyte imbalance, intracranial hemorrhage should be considered if seizures persist despite glucose control.

### Respiratory Care

Respiratory distress assessment is made by SA score (preterm) or Downes score (term). Oxygen is started if there is respiratory distress and the SpO<sub>2</sub> is not maintained. Sepsis screen, blood culture, blood sugar are done on admission as indicated. Chest X-ray defines the underlying cause of respiratory distress. ABG is done to assess the metabolic and respiratory status. Apnea, worsening sensorium, irregular breathing and inability to maintain oxygen saturation despite oxygen supplementation warrants initiation of artificial respiratory support. 2D echo and cardiology consult may be indicated if there is murmur, refractory hypoxia, unexplained shock or differential cyanosis. Paradoxical breathing pattern should raise suspicion of diaphragmatic paralysis which can be confirmed by fluoroscopy or ultrasound. Blood pressure is supported with fluid bolus, inotropes as needed. Bilirubin levels

should be measured if the infant appears to be jaundiced and hematocrit in first few hours and managed as hospital protocol.

### Birth Injury

X-ray long bones detect fractures, dislocation or humeral epiphyseal separation. Many fractures (clavicle or long bones) require no special treatment other than the simple measure of immobilization by slings, using paracetamol for pain control and advising parents not to grab the neonate or attempt to pick newborn up by the affected limb. For facial nerve palsy, patching the affected eye and lubricating eye drops are used. Facial nerve palsy generally improves within days after birth, but full recovery may take weeks to months and surgery restricted to cases with no full spontaneous recovery. In case of brachial plexus injury, protect the affected arm of the neonate is protected from dangling when moving or holding the neonate and parents told not to lift the neonate under the axillae. Physical therapy may be initiated with passive range of motion exercises at 1 week of age and no later than 3 weeks of age. Surgery may be necessary after 3 months if there is extensive damage to the nerve. EMG, nerve conduction, myelography, MRI may help define lesion at 1–4 months of age, but physical exam remains the ultimate guide to assess recovery and decide on surgical interventions.

### Counseling

The risk of obstetric and neonatal complications increases with rising birthweight. These risks need to be addressed during pre- and postdelivery counseling. Most genetically affected infants are diagnosed during pregnancy on ultrasound. The counseling should include a discussion on confirmation of diagnosis, survival, quality of life and risk of recurrence.

### OUTCOME

Neonatal morbidity and mortality is higher in LGA than in AGA infants for term and post-term but not for preterm babies. The risk increases as the birth percentile rises (**Table 6**). Large for gestational age pregnancies are associated with an increased rate of cesarean section, PPH, shoulder dystocia and neonatal hypoglycemia, as well as longer hospitalization. Simple fractures generally heal without complications. Majority of brachial plexus palsy recover on their own, but it depends on the degree of damage. Traumatic facial nerve palsy may improve within days,

with full recovery potentially taking months, possibly even years, depending on the severity. The most dismal prognosis associated with LGA neonates is for spinal cord injury.

Adverse outcomes are likely with prolonged or severe hypoglycemia and moderate to severe asphyxia requiring close neurodevelopmental follow-up. LGA neonates continue to grow longer and heavier and longitudinal data from developed countries convincingly associates macrosomia with long-term metabolic complications, including childhood obesity and the metabolic syndrome in adulthood. However no cognitive function differences compared to normal weight babies have been noted.

### PREVENTION

No intervention has been proven to significantly reduce the risk of macrosomia. Potentially useful strategies include prevention of maternal obesity before pregnancy with appropriate education and lifestyle modification, essential obstetric care, early assessment for gestational diabetes, tight glucose control during pregnancy, institutional delivery and skilled perinatal care, routine glucose screening, early recognition and prompt intervention for complications like asphyxia, hypoglycemia. It is possible that macrosomia is genetically programmed and cannot be altered by antepartum interventions.

#### IN A NUTSHELL

1. Large for gestational age (weight > 90th percentile) is an important risk factor for obstetric, neonatal and long-term metabolic complications. The risk increases as the birth percentile rises.
2. The use of risk factor information to identify mothers at risk of having large for gestational age births is an important clinical tool to meet individual needs by *anticipating* and providing the appropriate perinatal care.
3. Accurate anthropometric measurements and plotting them on appropriate growth charts is must. A focused physical assessment is vital.
4. Early identification and prompt management of feeding, traumatic birth injury, asphyxia, hypoglycemia, jaundice and polycythemia helps improve outcomes.

## Chapter 13.7

# Multiple Gestations

Mamta Jajoo

The human female is programmed to ovulate once during every menstrual cycle and results in fertilization of a single ovum, to take care of one fetus and one neonate at a time. This happens in 99.2% of the cases, but in the remaining 0.8%, more than one zygote is ovulated resulting in twins or rarely high-order multiple gestations (MGs).

Multiple gestations became more common because of increasing maternal age and implementation of induction ovulation therapy and assisted reproductive technologies (ARTs). Studies from developed countries show that, because of ARTs, the rate and number of twins and higher-order multifetal births have increased with frequencies approaching 50% for twins and more than 75% for high-order MGs. No exact data showing the effect of ARTs on the rate and number of MGs is available from India, probably due to lack of registry in infertility clinics.

Multiple gestations are associated with increased maternal, fetal, and neonatal complications. It has been found, that compared to singletons, risk of pre-eclampsia, postpartum hemorrhage and maternal deaths were 2–3 times more in MGs. MGs are also at increased risk of preterm and very low birthweight delivery. Multifetal pregnancies generate a medical, psychological and economic burden to families and society, especially in developing countries, due to scarcity of human resources and proper health infrastructure.

### PATHOPHYSIOLOGY

Twin fetuses can be monozygotic (MZ) or dizygotic (DZ). Most MZ conceptions result in singleton births but in 0.4% cases, the zygote splits to form MZ or identical twins. The mechanism of zygotic splitting is unclear but is also increased with methods of assisted reproduction. The outcome of MZ twinning process depends on the time of division. If zygote divides within the first 3 days of fertilization, two embryos, two amnions and two chorions develop, that is diamniotic dichorionic pregnancy evolves. Approximately, 30% of MZ twins have dichorionic (DC) diamniotic placenta. If division occurs between 4 days and 8 days, it results in a diamniotic monochorionic twin pregnancy. If division occurs after 8 days of fertilization, it results in monoamniotic and monochorionic twin pregnancy. Embryonic division after 13 days results in conjoined twins.

Dizygotic or fraternal twins result from multiple ovulations and the subsequent fertilization of two ova by two different spermatozoa. DZ twins have two placentas with two chorions and two amnions called DC placenta. If twins are of a different sex, they are DZ; however, if they are of the same sex, they can be MZ or DZ. The ratio of MZ and DZ twins varies from population to population.

### Higher Multiples

Multiple pregnancies with higher number of fetuses can arise from fertilization of one, two or more ova and division of one or more fertilized ova, which results in multiple pregnancies that can be simultaneously dizygous and monozygous.

### Superfecundation and Superfetation

*Superfecundation* is fertilization of second ova within the same menstrual cycle when one ovum has already being fertilized. *Superfetation* is fertilization and subsequent development of an embryo during the course of an established pregnancy.

### INCIDENCE

Estimates of incidence of MGs are incomplete in the developing countries where the frequencies of twin deliveries are high with poor birth registrations, unknown number of abortions and early fetal death. The incidence of spontaneous twins is approximately 1 in 80 pregnancies. For spontaneous triplets, the estimated incidence is 1 in 8,000 and for quadruplet births, approximately 1 in 600,000 births. Differences in twinning rates among countries are mostly due to variation in DZ twinning. The MZ twinning is approximated to occur at a relatively constant rate of 3.5–4 per 1,000 births across human population.

Dizygotic comprises of 67% of spontaneous twins and they have the same genetic similarities as between any two siblings. The overall DZ twin's rate varies from 4 to 50 per 1,000 worldwide: minimum 1.3% in Japan, and maximum 49% in Nigeria and 8.1% in India. According to a recent retrospective analysis of Demographic and Health Survey data of 76 developing countries, done over a period of 14 years, the average of the natural twinning rate in these countries was 13.1 per 1,000 and in India, incidence of twinning was about 9 per 1,000, a huge variation was found in twinning rates across the different regions of the countries surveyed.

According to this survey, in India, the increase in incidence of twinning over a period of 14 years was no more than 0.84 per 1,000 births, which is very small and nonsignificant. This suggests that influence of infertility treatment is still low in India.

### ETIOLOGY

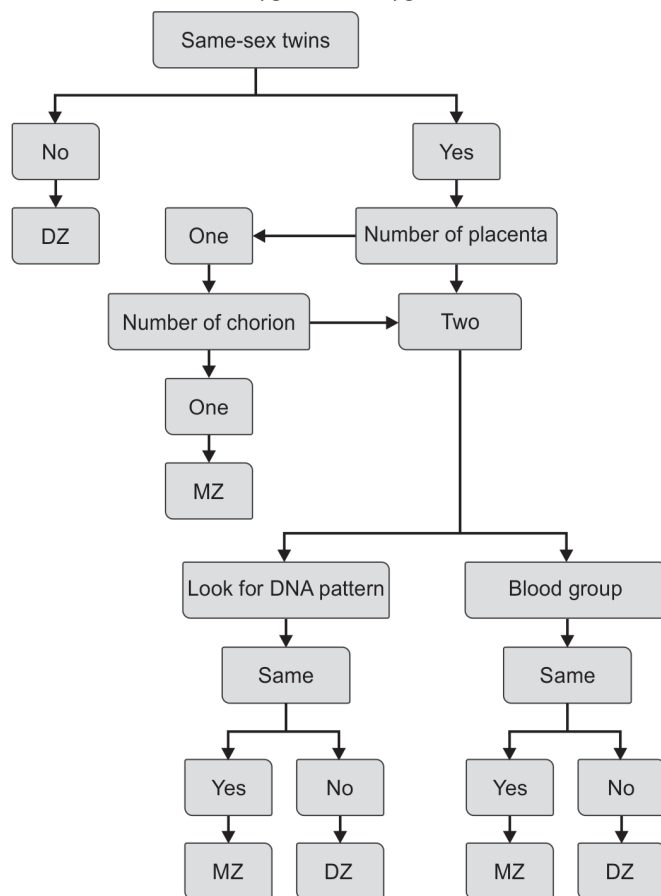

There are no known factors affecting the rate of MZ twinning but following ovarian stimulation or effect of assisted reproduction technology, it is 6–12 times more common. Many factors affect the rate of DZ twinning, like maternal age, race, ethnicity, heredity, parity, maternal nutrition level, infertility treatment and ovulation induction therapies. Important factor associated with twinning is maternal age. The number of twin pregnancies increases substantially with maternal age due to overstimulation by follicle-stimulating hormone and the luteinizing hormone surge.

### DETERMINATION OF ZYGOSITY AND CHORIONICITY

It is necessary to determine zygosity not only for epidemiological, genetic, obstetric and pediatric reasons but also because of the difference in prognosis between MZ and DZ twins as most of the complications occur in monochorionic MZ twins. It should be done routinely in all multiple pregnancies. Diagnosis of zygosity and chorionicity in antenatal period is important for the antepartum management of associated potential complications of twins like twin-to-twin transfusion, congenital anomalies, intrauterine growth restriction (IUGR) and demise of one fetus. It can be diagnosed by using ultrasound markers including the number of placental sites, thickness of dividing membrane, the lambda sign and fetal gender. At 10–14 weeks of gestation, ultrasound criteria correctly diagnose chorionicity in 99.3% of cases which is confirmed by postpartum placental examination.

Careful examination of placenta, physical similarity questionnaires, detail blood typing, tissue typing and human leukocyte antigen typing can also be used for determination of chorionicity (**Flow chart 1**). In twins of same sex, zygosity should be determined and recorded at birth. If the twins are of unlike sex, they are DZ and when a monochorionic placenta is found, they are MZ. DZ twins with same gender cannot be distinguished with MZ twins with DC placenta. In half of the DZ twins with same sex and one third of MZ twins with DC placenta, we are blind to zygosity (**Fig. 1**).

**Flow chart 1** Approach to diagnosis of monozygotic and dizygotic twins

Abbreviations: DNA, deoxyribonucleic acid; MZ, monozygotic; DZ, dizygotic.

**Figure 1** Relationship between zygosity and chorionicity

### Examination of Placenta

A careful placental examination after delivery establishes zygosity and chorionicity in approximately two-thirds of cases. Placenta should be carefully delivered to preserve the attachment of amnion and chorion. In DC placenta, dividing septum appears thicker and includes two amnions and two chorionic layers. In contrast, in monochorionic placenta the dividing septum consists of two thin amnions. One placenta, same-sex fetuses, and absence of a dividing septum suggests monoamniotic twins, but absence of a dividing septum may also be due to septal disruption.

## DIAGNOSIS OF MULTIPLE FETUSES

Early diagnosis is important for optimal antepartum management of fetuses. Taking a careful history and physical examination is useful in detecting multiple pregnancies. Family history or maternal personal history of twins, advanced maternal age, high parity and history of ingestion of clomiphene citrate, gonadotropins or pregnancy achieved by ARTs are more associated with MGs. Uterine size, and auscultation of two fetal hearts are helpful for a clinical diagnosis. Prenatal ultrasonography is used to confirm multifetal pregnancy and to monitor intrauterine fetal growth. It also helps in knowing the correct location of placenta and number of sacs. Without ultrasonic screening, the diagnosis is missed in 50% of the cases until the beginning of labor or delivery of one twin. Elevated maternal serum  $\alpha$ -fetoprotein and increased human chorionic gonadotropins in plasma and urine are present with MGs. Differential diagnosis of the large-for-date pregnancy includes inaccurate dating, hydramnios, hydatiform mole, uterine leiomyoma, fetal macrosomia or adnexal masses.

## PREGNANCY OUTCOMES

### Maternal Complications

Maternal mortality and morbidity increase many fold in a multifetal gestation. MGs are at increased risk for maternal complications like anemia, pregnancy-induced hypertension, polyhydramnios, hyperemesis gravidarum, acute fatty liver of pregnancy, venous thromboembolism, postpartum hemorrhage, malpresentations, premature rupture of membranes, hypertensive disorders, gestation-induced diabetes mellitus, preterm labor and abnormal placentation.

### Fetal and Neonatal Complications

Spontaneous abortions are three times more in twins than singletons. The incidence of congenital malformation is 2-3 times more in multiples; this increase is primarily related to MZ twinning. Malformation rates of DZ twins are similar to singletons. Malformations in twins are categorized under four subheadings:

1. *Due to twinning:* Neural tube defects, congenital heart defects, holoprosencephaly, esophageal and anorectal atresia, genitourinary tract anomalies are more common.
2. *Due to MZ twins:* This is because of reversal of blood flow in vascular anastomosis. Examples include twin reversed arterial perfusion (TRAP) sequence, amniotic band syndrome, conjoined twins and twin embolization syndrome.
3. *Due to placental malformations:* Particularly more in monochorionic placenta, resulting in twin-to-twin transfusion and velamentous cord insertion.
4. *Due to fetal crowding:* Defects include congenital hip dislocation, talipes equinovarus.

## COMPLICATIONS UNIQUE TO TWINNING

### Monoamniotic Twins

Monoamniotic twins account for 1% of MZ twin pregnancies. Monoamniotic twins are at increased risks of morbidity and mortality of one or both twins because of cord compression as a result of cord entanglement.

### Twin Reversed Arterial Perfusion Sequence

Vascular anastomosis between fetuses are frequent in monochorionic twin which may be from artery to artery, vein to vein, vein to artery. They are usually hemodynamically balanced but sometimes significant shunts develop between fetuses. In TRAP sequence, one twin transfuses its co-twin via an arterioarterial shunt; hence transfused twin receives blood by an artery instead

of vein giving rise to reversed perfusion. The donor twin is usually normally formed fetus, who has heart failure, and a recipient twin who lacks heart (acardius) and other structures, called acephalic-acardiac twin. Without treatment, the death rate of donor twin ranges from 50% to 75%. TRAP is very rare and occurs in 1 out of 35,000 births.

### Twin-to-twin Transfusion Syndrome

Twin-to-twin transfusion syndrome occurs in 20% of monochorionic twins. It is thought to occur secondary to placental vascular anastomoses. This leads to increased blood flow to one fetus (recipient fetus) and reduced blood flow to the other one (donor fetus). It is usually diagnosed by ultrasound in the second trimester with the appearance of oligohydramnios in the donor and polyhydramnios in the recipient twin. In the classic twin-to-twin transfusion syndrome, there is difference of 5 g/dL in hemoglobin levels and birthweight discrepancy of at least 20% can be present between two twins. There are other associated signs, such as plethora and hydrops in the recipient twin and pallor, malnourishment, and hypoxic damage in the donor twin. Perinatal mortality in twin-to-twin transfusion syndrome is as high as 70%. Several therapies have been used including serial amnioreduction and laser coagulation of the communicating vessels. Laser treatment is more effective than amniocentesis. In neonatal period, the donor shows signs of anemia, hypoproteinemia and intrauterine growth retardation whereas the recipient twin is polycythemic, heavier, and has complications of hyperviscosity, intravascular thrombosis and hyperbilirubinemia. Postnatal treatment is same as of polycythemia or anemia for singleton with the same problems. Risk of brain damage and periventricular leukomalacia is high in a recipient twin.

### Conjoined Twins

It is very rare and occurs approximately in 1 in 50,000 pregnancies. It occurs in MZ twins in which the division of the zygote is incomplete. Good visualization with two-dimensional or three-dimensional ultrasound and color Doppler assessment in antenatal period helps in delineating the site and extent of the fusion.

### Chromosomal Anomalies

Heterokaryotypes and misdistributions of chromosomes occur more during the twinning process which lead to a higher frequency of chromosomal anomalies in twins. The risk in MZ twins is equivalent to that of a singleton. The risk in DZ twins is independent for each fetus, so the risk of chromosomal abnormality in at least one DZ twin is twice that of a singleton fetus. Advanced maternal age also increases the risks of chromosomal anomalies in MG fetuses.

### Fetal Brain Damage

Neurological damage like cerebral palsy, microcephaly, porencephalic cysts more common in fetus of MG pregnancies, and is most likely caused by ischemic necrosis secondary to blood pressure instability and episodes of severe hypotension.

### Discordant Twins

It is the most common growth aberration in multiples. Discordance in growth is defined as the percent definition, when the larger fetus weighs 20% more than the smaller fetus. Etiology of discordant twin is unclear, but it is different in monochorionic and DC twins. In monochorionic twins, it is caused by placental vascular anastomosis that causes hemodynamic instability and in DC twins; it is mainly due to different genetic growth potential. Mortality is 11 times higher in highly discordant (>30%) twins. Birthweight discordance has been associated with increased risk of intrauterine and malformations related deaths.

### Intrauterine Growth Restriction

Intrauterine growth restriction is defined as an estimated fetal weight below the tenth percentile for singleton gestation. The growth restriction is more in MZs than DZs, compared to singletons; twins develop IUGR after 32 weeks of gestation and triplets after 29 weeks of gestation. Approximately, 14–25% of twin gestations and 50–60% of triplet or higher-order gestations are affected by growth restriction. Growth restriction in MGs is likely to be secondary to uteroplacental insufficiency but can also be secondary to structural anomalies, umbilical cord abnormalities, ultrasound error, infections, or genetic abnormalities.

### MANAGEMENT

Aim of the antenatal care is to prevent fetal growth retardation, premature delivery and to decrease the maternal complications. Antenatal care should be done every 2–3 weeks, monthly cranial ultrasonography after 24 weeks of gestation to assess fetal growth and weight and early detection of complications related to monochorionic placenta is required.

### Nonstress Test

A nonreactive nonstress test should be done; the results of an abnormal biophysical profile should be interpreted as for singleton pregnancy. The nonstress test may be impractical in all instances because of the difficulties of simultaneous assessment in three or more fetuses.

### Maternal Nutrition

Needs special care because of increased requirement of calories, minerals and vitamins in women with multiple fetuses.

### Prevention of Preterm Delivery

There is no evidence showing definite role of bed rest, cerclage and prophylactic tocolytics in prevention of preterm labor, but decreased physical activity after 20–24 weeks, helps in prevention of preterm labor.

### Timing of Delivery

Twins should be delivered by 36–37 weeks of gestational age (GA) because of two reasons. First, neonatal mortality and morbidity are increased after 37 or 38 weeks of GA and second, the fetal systems of MGs get matured by these dates. At present, there is great controversy exists regarding elective preterm delivery of monochorionic twins.

### Mode of Delivery

Due to increased maternal and neonatal complications in twins and high-order MGs, the delivery of higher-order MGs presents great challenges to obstetricians. Many clinicians preferred to deliver them by cesarean section. The decision depends on many other factors, e.g., fetal size, uterine discordance, prior uterine surgery and the experience and skills of obstetrician.

### OUTCOME

There is significant gap in the literature on the outcome of twin deliveries in developing countries where frequency of twin is high and research on multiple births is challenging.

### Perinatal Mortality

The perinatal mortality is over four times higher in twins and 4–9 times higher in triplets. According to a secondary analysis of the WHO global survey to analyze maternal and perinatal outcome in 23 low- and middle-income countries on twin gestation, it has been found that perinatal mortality is higher (7.1%) in twins than

singleton (2%). Increased perinatal mortality in twins may be due to increased intrauterine growth retardation, premature rupture of membrane, preterm deliveries and low birthweight and low Apgar scores. Stillbirth rate in twins is much higher than singleton mainly because of twin-to-twin transfusion syndrome. If one fetus dies in case of MZ twin, there is 20% risk of intrauterine death of co-twin. Mortality in MZ twin is higher than in DZ twins.

### Neonatal Mortality

Rates of neonatal mortality are GA specific and are similar for singletons, twins, and triplets. Prematurity and low birthweight are the predominating factors that increase the rates of mortality for multiple births. An increase in mortality rate was associated with monochorionic twin, especially after intrauterine fetal demise of one twin.

### Neonatal Morbidity

These complications are mainly related to prematurity and IUGR. As the gestation age decreases, incidence of respiratory distress syndrome increases. Compared with first-born twin, the second twin is at increased risk for respiratory distress syndrome, asphyxia and death. They are also associated with an increased risk of morbidities such as bronchopulmonary dysplasia, necrotizing enterocolitis, retinopathy of prematurity and intraventricular hemorrhage.

### Long-term Morbidity

Neurological outcomes also appear to be worse in multiple births. When matched for GA at delivery, infants born from multifetal pregnancies have an approximately threefold increase in cerebral palsy. The prevalence of cerebral palsy in twins is 7.4%, compared with 1% in singletons. This is primarily because of increased risk of prematurity and low birthweight in multiple births and high risk for cerebral injury in twins with monochorionic placentation and in those with twin-to-twin transfusion syndrome.

### Counseling of Parents

Parents need special counseling because of emotional, financial as well as practical issues involved with MGs. They are often not only associated with problems of caring of two babies but also with the problems of MGs like prematurity, low birthweight and other related neonatal morbidities. In situations where one baby is more demanding, and needs more attention than other, mother should not feel guilty and should be reassured.

Physicians should try to discharge both the babies together; otherwise baby left behind may suffer in his relationship with parents. Mothers should be encouraged to exclusively breastfeed both the neonates, she should be educated about proper positioning and attachment and technique to feed two babies simultaneously. Simultaneous feeding is time efficient and stimulates the let-down reflex for weaker infant.

### Prognosis

Most of the multiple neonates are at high-risk, they need regular follow-up in high-risk follow-up clinic for routine screening of hearing, vision, growth and development. Early stimulation therapy should be started at term corrected gestation age.

#### IN A NUTSHELL

1. Multifetal pregnancies generate a medical, psychological and economic burden to families and society.
2. Increase in multiple pregnancies is a public health concern; they have 5–10 times higher risk of complications than do singletons.
3. There is higher incidence of maternal, fetal and neonatal mortality.
4. Frequent prenatal visits should be advised. Serial ultrasound examinations (every 3–4 weeks) must be done to detect any growth abnormalities. If diagnosed, additional antenatal ultrasonography is important to monitor the pregnancy, to detect growth discrepancies, zygosity, and the fetofetal transfusion.
5. Early diagnosis and management of maternal and fetal morbidities are most important for the better outcome of MGs.
6. Providing care to women and neonates with multiple pregnancies constitutes a challenge especially in developing countries to the obstetricians, and neonatologists because of limited resources and infrastructure.
7. Education and counseling of parents are very important for a better long-term outcome of MGs neonates.

# Section 14 HIGH-RISK NEWBORN

**Section Editor** Siddarth Ramji

## Chapter 14.1

### Recognition of High-Risk Neonate

Niranjan Thomas, Vijay Gupta

*Who are high-risk neonates?* Neonates with an increased likelihood of mortality or morbidity because of any preconceptional, prenatal, natal or postnatal condition that interferes with normal birth process, impairs extrauterine transition or impedes postnatal growth and development are called high-risk newborns.

Anticipation and early intervention will prevent the development or progression of more serious illness and will minimize the risk of morbidity and mortality in this vulnerable group. Most high-risk infants can be identified before birth based on maternal history (e.g., maternal diabetes, multiple gestations, preterm labor, etc.), while others are identified in the delivery room based on clinical assessment (e.g., small for gestational age, large for gestational age, congenital malformations, respiratory distress syndrome, asphyxia, etc.) or in the postnatal wards/homes because of certain symptoms and signs (e.g., cyanosis, jaundice, poor feeding, etc.).

Risk factors (antenatal, intranatal and postnatal) that increase neonatal morbidity and mortality, making a newborn high-risk, and their effects on the fetus/newborn are summarized in **Tables 1 to 3**.

## ASSESSMENT AND DIAGNOSIS

### Antenatal Risk Factors

It is essential to obtain a complete maternal history to anticipate and prepare for a high-risk delivery. The prenatal record, current hospital chart and laboratory studies should be reviewed for known risk factors (**Table 1**). Maternal age of conception, nutritional status, personal social status, systemic diseases and infections predispose the fetus to preterm delivery, intrauterine growth restriction (IUGR) or intrauterine fetal demise. During the antenatal period, a high-risk fetus can be identified by several assessments and screening tests as discussed below:

#### Gestational Age Assessment

Gestational age assessment is important as prematurity contributes significantly to neonatal mortality and morbidity. This is usually based on the last menstrual period (LMP) or an early scan. Early ultrasound scan between 10 weeks and 12 weeks have the best predictive value (92%), while dating based on scans less than 20 weeks measuring the crown rump length (CRL) and biparietal diameter (BPD) provides a better estimate of gestational age as compared to LMP (predictive value 89–92%). However, after 24 weeks, reliable LMP provides a better estimate as compared to ultrasound. Early ultrasound scans using CRL precisely estimate

the gestational age with accuracy of  $\pm 5$  days and  $\pm 7$  days at 10 and 12 weeks, respectively. BPD estimates the gestational age with accuracy of  $\pm 10$  days,  $\pm 14$  days and  $\pm 21$  days at 20 weeks, 30 weeks and 40 weeks of gestation, respectively.

#### Ultrasound Screening

Ultrasonography is a useful tool in the assessment of the high-risk fetus and can be used at different times during the pregnancy as given below:

*First-trimester nuchal translucency screening* Ultrasonographic assessment of the fluid collected at the nape of the fetal neck is a sensitive marker for aneuploidy which can identify 76.8% of fetuses with trisomy 21, with false-positive rate of 4.2%.

*Anomaly screening* Ultrasound screening is performed at 20–22 weeks of gestation to rule out structural malformations in the fetus. In the absence of structural malformations, the markers associated with an increased risk of fetal growth restriction/IUGR and aneuploidies include bright or echogenic fetal bowel, single umbilical artery, isolated short femur (where the femur length is below the fifth percentile for gestational age but the abdominal circumference measurements and the estimated fetal weight are within the normal range).

*Doppler velocimetry* Umbilical artery Doppler evaluation after 16 weeks of gestation is useful in monitoring the pregnancy that is associated with maternal disease (hypertension or diabetes), uteroplacental insufficiency, and fetal growth restriction. The development of absent (AEDF) or reversed end-diastolic flow (REDF) (**Figures 1A and B**) in the umbilical artery is regarded as an ominous finding and is associated with fetal hypoxia and fetal acidosis with subsequent adverse perinatal outcome. The odds of increased perinatal mortality in pregnancies complicated by AEDF and REDF are 4.0 and 10.6, respectively. These indices in the umbilical artery will rise when 60–70% of the vascular tree has been altered. Fetal middle cerebral artery Doppler is presently the best tool for evaluating for the presence of fetal anemia in at risk pregnancy like Rh isoimmunization.

#### Serum Markers

Alteration in the levels of various serum and amniotic fluid markers (**Table 4**) during first and second trimester of pregnancy individualizes a woman's risk of carrying a high-risk fetus. Women carrying fetus with trisomy 21 can be identified using first- and second-trimester serum screen. In the first trimester (11–14 weeks) it is marked by decreased levels of pregnancy-associated plasma protein-A (PAPP-A) and increased levels of free beta-human chorionic gonadotropin ( $\beta$ -hCG). In the second trimester (15–20 weeks), triple test [ $\uparrow\beta$ -hCG,  $\downarrow$ alpha-fetoprotein and  $\downarrow$ unconjugated estriol (uE3)] has a sensitivity of about 60%, and the quadruple test ( $\uparrow\beta$ -hCG,  $\downarrow$ AFP,  $\downarrow$ uE3 and  $\uparrow$ inhibin A levels) has a sensitivity of approximately 67–76% in diagnosing a fetus with trisomy 21 in women less than 35 years of age. The sensitivity of triple test increases to more than 75% when performed in women more than 35 years.

**Table 1** Antenatal risk factors

<i>Maternal risk factors</i>	<i>Risk to fetus/newborn</i>
<i>Age at delivery</i>	
Age <16 years	IUGR, prematurity
Age >40 years	Chromosomal abnormalities, macrosomia, IUGR, blood loss (abruption or previa)
<i>Personal/social factors</i>	
Lower socioeconomic status	Prematurity, IUGR, infection
Illiteracy	Low birth weight
Smoking	Increased perinatal mortality, IUGR
Drug abuse and alcohol use	IUGR, fetal alcohol syndrome, withdrawal syndrome, sudden infant death syndrome
Physical or psychological stress	IUGR, low birth weight, prematurity
<i>Maternal nutrition</i>	
Poor diet/maternal malnutrition	IUGR, fetal demise in severe malnutrition
Obesity	Macrosomia, birth trauma, hypoglycemia
Vitamin D deficiency	Neonatal hypocalcemia, rickets
<i>Assisted reproductive technology</i>	
In vitro fertilization, intracytoplasmic sperm injection	Increases the risk of perinatal mortality, infant morbidity, prematurity, low and very low birth weight, increased risks for birth defects and cerebral palsy
<i>Obstetric history</i>	
Poor weight gain during pregnancy	IUGR
Short interpregnancy interval	Prematurity
Bleeding in early pregnancy	Stillbirth, prematurity
Uterine bleeding (abruption, placenta previa)	Premature delivery, asphyxia
Uterine or cervical anomaly	Prematurity
Trauma (acute, chronic)	Abruptio placentae, fetal demise, prematurity
Premature rupture of membranes	Infection/sepsis
Polyhydramnios	<i>Neurological anomalies:</i> Anencephaly, hydrocephalus, spina bifida and other central nervous system (CNS) disorders and Neuromuscular disorders. <i>Other congenital anomalies:</i> Duodenal atresia, cystic adenomatoid lung malformation, chylothorax, diaphragmatic hernia, omphalocele, gastroschisis, tumors (teratoma) <i>Problems with swallowing</i> (e.g., agnathia, any mass in the mouth, cleft lip or palate, esophageal atresia with tracheoesophageal fistula) <i>Other causes:</i> Hydrops fetalis, isoimmunization, anemia, cardiac failure, polyuric renal disease, large for gestational age, Infant of diabetic mother, Twin-twin transfusion (recipient), Syndromes (e.g., Achondroplasia, Klippel-Feil, trisomies 18 and 21), intrauterine infection e.g., TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex)"
Oligohydramnios	Fetal demise, placental insufficiency, IUGR, deformations, intrapartum distress, post-term delivery, fetal anomalies, twin-twin transfusion (donor), renal agenesis (Potter syndrome), urethral atresia, prune belly syndrome, pulmonary hypoplasia, amnion nodosum, intestinal pseudo-obstruction
Hyperthermia	Fetal demise, fetal anomalies
Previous pregnancy with intrauterine fetal demise, neonatal death, prematurity, respiratory distress syndrome, IUGR, congenital malformation, incompetent cervix, blood group sensitization, neonatal jaundice, neonatal thrombocytopenia, hydrops, inborn error of metabolism	Same with current pregnancy
<i>Medical disease: Systemic</i>	
Systemic cardiovascular or respiratory problems	Stillbirth, IUGR, prematurity
Hypertension (chronic or pregnancy-related)	Stillbirth, IUGR, prematurity, asphyxia
Cholestasis/liver disease	Preterm delivery, intrauterine fetal demise
Inflammatory bowel disease	Prematurity, IUGR
Renal disease	Stillbirth, IUGR, prematurity
Renal transplantation	Intrauterine growth restriction (uteroplacental insufficiency)

Contd...

Contd...

<b>Maternal risk factors</b>	<b>Risk to fetus/newborn</b>
Urinary tract infection	Prematurity, sepsis
Chronic periodontal disease	Preterm labor
Myotonic dystrophy	Neonatal myotonic dystrophy, congenital contractures, respiratory insufficiency
<i>Medical disease: Endocrinal</i>	
Diabetes mellitus	Congenital anomalies like: Congenital heart disease, limb abnormalities, CNS anomalies, small left colon syndrome, femoral hypoplasia-unusual facies syndrome, caudal regression syndrome Fetal macrosomia, birth trauma, stillbirth, hypoglycemia, hyperbilirubinemia, polycythemia, cardiomyopathy Respiratory distress syndrome (RDS) and growth restriction
Hypoparathyroidism	Fetal hypocalcemia, neonatal hyperparathyroidism
Hyperparathyroidism	Neonatal hypocalcemia and hypoparathyroidism
Graves' disease	Fetal and neonatal hyperthyroidism, intrauterine growth restriction, prematurity
Endemic goiter/hypothyroidism	Goiter, hypothyroidism, hyperthyroidism
Herpes gestationis (noninfectious)	Bullous rash, intrauterine fetal demise
<i>Medical disease: Hematological</i>	
Anemia (Hb < 6 g/dL)	Stillbirth, IUGR, hydrops, prematurity, asphyxia
Iron deficiency anemia	Lower mental and developmental scores in follow-up
Sickle cell anemia	Prematurity, IUGR, stillbirth
Idiopathic thrombocytopenic purpura	Thrombocytopenia, CNS hemorrhage
Alloimmunization (fetal platelet antigen sensitization)	Thrombocytopenia, CNS hemorrhage, stillbirth
Isoimmune neutropenia	Neutropenia
Isoimmunization (red cell antigens)	Stillbirth, hydrops, anemia, jaundice, hypoalbuminemia
Maternal hypercoagulable states	Fetal demise
Thrombocytopenia	Stillbirth, bleeding
<i>Medical disease: Autoimmune</i>	
Autoantibody against folate receptors	Neural tube defects
Myasthenia gravis	Transient neonatal myasthenia
Systemic lupus erythematosus	Congenital heart block, rash, anemia, thrombocytopenia, neutropenia, neonatal lupus
<i>Medical disease: Inborn errors of metabolism</i>	
Phenylketonuria (poorly controlled)	Microcephaly, retardation, congenital heart disease
<i>Medical disease: Neoplastic</i>	
Cervical neoplasia	Preterm premature rupture of membranes
Malignant melanoma	Placental or fetal tumor (metastasis)
<i>Fetal characteristics</i>	
Multiple gestation	IUGR, twin-twin transfusion syndrome, prematurity, birth trauma, asphyxia Monozygotic twins are 2–3 times more likely to have structural defects than singletons and dizygotic twins
IUGR	Fetal demise, congenital anomalies, perinatal depression, meconium aspiration, pulmonary hemorrhage, persistent pulmonary hypertension, hypotension, hypoglycemia, hypocalcemia, hypothermia, dyslipidemia, polycythemia, neutropenia, thrombocytopenia, acute tubular necrosis/renal insufficiency
Preterm delivery	RDS, patent ductus arteriosus, hyperbilirubinemia, intraventricular hemorrhage, retinopathy of prematurity, hypothermia, hypoglycemia, chronic lung disease, necrotizing enterocolitis, apnea of prematurity, other issues of preterm birth
Macrosomia/large for gestation	Congenital anomalies, birth trauma (cervical and brachial plexus injuries, phrenic nerve damage with paralysis of the diaphragm, fractured clavicles, cephalohematomas, subdural hematomas, and ecchymoses of the head and face), hypoglycemia, polycythemia
Post-term delivery/postmaturity syndrome	Stillbirth, asphyxia, perinatal depression, oligohydramnios, nonreassuring fetal heart rate tracing in labor, fetal macrosomia, birth injury, meconium aspiration, persistent pulmonary hypertension, hypoglycemia, hypocalcemia, and polycythemia
Abnormal fetal position/presentation	Congenital anomalies, birth trauma, hemorrhage, asphyxia

Abbreviation: IUGR, intrauterine growth restriction.

**Table 2** Intrapartum risk factors

<i>Maternal risk factors</i>	<i>Risk to fetus/newborn</i>
Maternal fever	Infection/sepsis
Maternal hypotension	Stillbirth, asphyxia
Rapid labor	Birth trauma, intracranial hemorrhage (ICH), retained fetal lung fluid/transient tachypnea
Prolonged labor >24 hours	Stillbirth, asphyxia, birth trauma
Prolonged second stage labor >2 hours	Perinatal depression
Cord prolapse	Stillbirth, asphyxia
Uterine tetany/rupture	Asphyxia
Meconium-stained amniotic fluid	Stillbirth, asphyxia, meconium aspiration syndrome, persistent pulmonary hypertension
Foul smelling of amniotic fluid/membranes	Infection
Obstetric analgesia and anesthesia	Respiratory depression, hypotension, hypothermia
Cesarean delivery	RDS, retained fetal lung fluid/transient tachypnea, blood loss
Elective LSCS < 39 weeks gestation	Increased rates of adverse respiratory outcomes, mechanical ventilation, newborn sepsis, hypoglycemia
<i>Fetal characteristics</i>	
Abnormality of fetal heart rate or rhythm	Congestive heart failure, heart block, hydrops, asphyxia
Persistent fetal tachycardia	Infection, maternal fever and medications
Fetal bradycardia	Congenital heart block associated with congenital heart malformation or maternal systemic lupus erythematosus
Loss of beat-to-beat variability in FHR	Depressed fetal central nervous system due to fetal immaturity, hypoxia, fetal sleep, or maternal medications
Decreased fetal movements	Fetal demise, asphyxia
<i>Placental anomalies</i>	
Small placenta	IUGR
Large placenta	Hydrops, maternal diabetes, large infant
Torn placenta and/or umbilical vessels	Blood loss
Short umbilical cord (< 40 cm)	Fetal akinesia sequence, respiratory insufficiency, pulmonary hypoplasia (Pena-Shokeir syndrome)
Abnormal attachment of vessels to placenta	Blood loss

Abbreviations: RDS, respiratory distress syndrome; IUGR, intrauterine growth restriction; FHR, fetal heart rate; LSCS, lower segment cesarean section.

**Table 3** Postnatal risk factors

<i>Risk factors: failed intrauterine to extrauterine transition</i>	
<i>Presenting features</i>	<i>Risk to newborn</i>
Respiratory distress	Respiratory morbidity like hyaline membrane disease, meconium aspiration syndrome, persistent pulmonary hypertension, air leak syndrome, early neonatal sepsis (pneumonia), transient tachypnea of newborn, chylothorax, pleural effusion, pulmonary hypoplasia, mechanical airway obstruction, perinatal asphyxia, congenital diaphragmatic hernia and other congenital lung malformations
Apnea soon after birth/crying	Extreme prematurity, congenital diaphragmatic hernia, pneumothorax, vagal stimulation (deep suction), perinatal asphyxia, neonatal seizure, inborn error metabolism
Cyanosis	Respiratory morbidities, critical congenital heart disease, methemoglobinemia, CNS malformations, perinatal asphyxia
Pallor/shock	Perinatal asphyxia, occult blood loss, myocardial dysfunction
Hypotonia	Perinatal asphyxia, neuromuscular disease, CNS malformation, inborn error metabolism
Low 5-min Apgar score	Prolonged transition (especially respiratory)
Low 10–15-min Apgar score	Perinatal depression and asphyxia, neuromuscular disorder
<i>Risk factors: congenital anomalies/birth injury</i>	
<i>Presenting features</i>	<i>Risk to newborn</i>
Caput succedaneum, cephalohematoma, subgaleal bleed	Birth injury

Contd...

Contd...

Dysmorphic features	Syndromes
Asymmetric crying facies	Congenital absence of the depressor anguli oris muscle (DAOM), facial palsy
Cyanosis improving with cry	Bilateral choanal atresia
Frothing	Tracheoesophageal fistula
Asymmetric Moro reflex	Erb's palsy, fracture clavicle, fracture humerus
"Frog" posture or generalized hypotonia	Congenital myopathy, severe HIE, inborn error of metabolism
Scaphoid abdomen	Congenital diaphragmatic hernia, meconium aspiration syndrome
Ambiguous genitalia	Congenital adrenal hyperplasia, disorders of sex development
Imperforate anus	Anorectal malformation
Single umbilical artery	IUGR, renal abnormalities
<b>Risk factors: neonatal morbidities</b>	
<i>Presenting features</i>	<i>Risk to newborn</i>
IUGR	Fetal demise, congenital anomalies, perinatal depression, meconium aspiration, pulmonary hemorrhage, persistent pulmonary hypertension, hypotension, hypoglycemia, hypocalcemia, hypothermia, dyslipidemia, polycythemia, neutropenia, thrombocytopenia, acute tubular necrosis/renal insufficiency
Preterm delivery	RDS, patent ductus arteriosus, hyperbilirubinemia, intraventricular hemorrhage, retinopathy of prematurity, hypothermia, hypoglycemia, chronic lung disease, necrotizing enterocolitis, apnea of prematurity and other issues of preterm birth
Hypothermia (temperature less than 95°F or < 35°C)	Sepsis, cold stress
Fever (temperature >100°F)	Sepsis, hypoxic ischemic encephalopathy, dehydration
Lethargy/poor suck/not feeding well	Sepsis, hypoglycemia, dyselectrolytemia, perinatal depression, hypoxic ischemic encephalopathy, inborn error of metabolism
Sharp weight loss	Dehydration, sepsis
Jaundiced within 24 hours of life	ABO, Rh, minor blood group incompatibility, polycythemia, G6PD deficiency, red cell membrane and enzyme defects, prematurity
Bulging anterior fontanel	Meningitis, hydrocephalus
Shrill cry/twitching	Sepsis, meningitis, intraventricular hemorrhage, neonatal seizures
Convulsions	Sepsis, meningitis, intraventricular hemorrhage, hypoglycemia, dyselectrolytemia, inborn error of metabolism
Pallor/shock	Concealed blood loss, shock, sepsis, hypoxic ischemic encephalopathy, anemia
Cyanosis	Circulatory failure, sepsis, critical congenital heart disease, hypoglycemia, methemoglobinemia
Apnea	Sepsis, neonatal seizures, hypoglycemia, dyselectrolytemia, extreme prematurity, hypothermia, hyperthermia, CNS malformation, hypoxic ischemic encephalopathy, anemia
Drizzling of saliva	Tracheoesophageal fistula, neonatal seizures, myopathies
Rapid or labored breathing or irregular respiration	Sepsis, pneumonia, aspiration, meconium aspiration syndrome, air leaks, transient tachypnea of newborn, circulatory compromise, congestive cardiac failure, hypoglycemia, hypoxic ischemic encephalopathy, inborn error metabolism
Grunting	Hyaline membrane disease, sepsis, pneumonia, aspiration, meconium aspiration syndrome, air leaks, circulatory compromise, congestive cardiac failure, hypoglycemia, hypoxic ischemic encephalopathy, inborn error metabolism
Abdominal distension, vomiting (bilious)	Sepsis, NEC, intestinal obstruction, volvulus/malrotation, meconium ileus, meconium plug, Hirschsprung disease, anorectal malformation
Sclerema	Sepsis
Bleeding from any sites	Hemorrhagic disease of newborn, sepsis, DIC, coagulopathy, thrombocytopenia
Edema	Renal failure, hydrops
Not passing urine within first 48 hours of life	Dehydration, obstructive uropathy, renal agenesis, renal failure
Not passing stools within first 24 hours of life	Passed in utero, meconium plug, anorectal malformation, hypothyroidism, Hirschsprung disease, intestinal obstruction/atresia

Abbreviations: CNS, central nervous system; IUGR, intrauterine growth restriction; RDS; respiratory distress syndrome; G6PD, glucose-6-phosphate dehydrogenase; NEC, necrotizing enterocolitis.

**Figures 1A and B** Umbilical artery Dopplers: showing (A) Normal flow and (B) Reverse end diastolic flow (REDF)

**Table 4** Maternal markers and risk to fetus

Maternal markers	Increased fetal risk
↑Amniotic fluid AFP and acetylcholinesterase (AChE)	Open neural tube defect
↑Serum AFP levels [ $>2.5$ MoM and $>3.5$ MoM for twins (15–20 weeks gestation)]	Neural tube defects (spina bifida, anencephaly, etc.) Abdominal wall defects (gastroschisis, omphalocele) Intestinal atresias (esophageal or intestinal obstruction) Renal anomalies, polycystic kidneys and renal agenesis Congenital nephrosis Osteogenesis imperfecta Congenital skin defects Cystic hygroma Cloacal exstrophy Pilonidal sinus Multifetal gestation Fetal demise Underestimated gestational age
↓Serum AFP levels (15–20 weeks of gestation)	Chromosomal trisomies Maternal diabetes Obesity Gestational trophoblastic disease Fetal demise Overestimated gestational age
↑β-hCG (10–20 weeks)	Trisomy 21
↓β-hCG (11–14 weeks)	Trisomy 13 and 18
↓PAPP-A (10–14 weeks)	Trisomy 21, 13, 18 or sex chromosomal abnormalities

Abbreviations: MoM, multiples of median; AFP, alpha fetoprotein; β-hCG, beta-human chorionic gonadotropin; PAPP-A, pregnancy-associated plasma protein-A.

### Monitoring of Fetal Well-being

**Fetal movements** Normal fetal movements are maternal perception of at least 10 fetal movements during 12 hours of normal maternal activity or at least ten fetal movements over 2 hours when the mother is at rest or at least four fetal movements in 1 hour when the mother is at rest and focused on counting. Periods of inactivity

more than 1 hour are unusual in a healthy fetus and should alert the physician to the possibility of fetal compromise.

**Nonstress test (after 32 weeks of gestation)** The nonstress test (NST) is performed by monitoring fetal heart rate (FHR) either through skin-surface electrodes strapped on to the maternal abdomen or using a Doppler ultrasonographic device. Uterine activity is simultaneously recorded using tocodynamometer, or palpation by trained personal, or the patient's report. It is based on the principle of reflex acceleration of FHR in response to fetal activity. A reactive NST is usually reassuring, with the risk of fetal demise being 3 per 1,000 in the next 7 days following the test. A nonreactive test is generally repeated later the same day or is followed by another test of fetal well-being like contraction stress test (CST) or an acoustic stimulation test (AST).

The criteria for a reactive test are as follows: (a) heart rate between 110 and 160; (b) normal beat-to-beat variability [5 beats per minute (bpm)]; and (c) two FHR accelerations of at least 15 bpm, lasting a total of 15 sec. Most NSTs are reactive within the first 20 min period, but an additional 20 min may be considered to account for fetal sleep cycle. A nonreactive test fails to meet these three criteria and there will be no acceptable acceleration (as defined by reactive NST) in 40 min period.

**Contraction stress test** The CST is based on the principle, that even brief reduction or elimination of intervillous perfusion during uterine contraction may result in brief hypoxia to the already compromised fetus resulting in FHR decelerations. A healthy fetoplacental unit has sufficient oxygen reserve to tolerate this brief hypoxic episode. If this fails, FHR begins to decelerate 15–30 sec after onset of the contraction, reaches its nadir after the peak of contraction, and does not return to baseline until after the contraction ends. This heart-rate pattern is known as a late deceleration or type II deceleration resulting from uteroplacental insufficiency.

Like NST, CST also monitors FHR and uterine contractions. A CST is considered completed if uterine contractions have spontaneously occurred within 30 min period with frequency of three within 10 min interval, lasting 40–60 sec each. Uterine contraction can be induced with intravenous oxytocin in absence of spontaneous contraction, when it is known as *oxytocin challenge test*.

A *CST is positive* if uterine contractions are associated with consistent late deceleration pattern. A CST is negative when at least three uterine contractions of at least 40 sec each, occur within a 10-min interval without associated late decelerations. The study is

considered hyperstimulated, if more than five uterine contractions occur in 10-min interval or each contraction last for more than 90 sec.

A *negative CST* is even more reassuring as compared to reactive NST, with the chance of fetal demise of approximately 0.4 per 1,000 within a week of negative CST. If a positive CST follows a nonreactive NST, the risk of stillbirth is about 88 per 1,000.

**Acoustic stimulation test** For a fetus showing a nonreactive NST, AST can be done by providing a brief exposure of vibroacoustic signal (devices emitting sound levels of approximately 80 dB at 80 Hz frequency for 1–3 sec) to the fetus. The sound emitting device called as artificial larynx is strapped over maternal abdomen to evoke FHR acceleration in response to fetal movements.

- **Reactive acoustic stimulation test:** Two FHR accelerations of at least 15 bpm, lasting a total of 15 sec, within 5 min after application of acoustic stimulus or an acceleration of at least 15 bpm above baseline lasting 120 sec.
- **Nonreactive acoustic stimulation test:** If after three applications of acoustic stimulation at 5-min intervals, no acceptable accelerations (as defined by reactive AST) occur for 5 min after the third stimulus.

Although the false-negative and false-positive rates (50–60%) are higher for an NST than a CST, it is easier to perform and therefore the method for first-line antenatal testing. The modified NST has become the initial testing procedure of choice, which comprises use of vibroacoustic stimulation during standard NST if no acceleration is noted in the preceding 5-min interval. The acoustic signal is repeated if 9 min have elapsed since the first acceleration (as reactive test is defined by the presence of at least two accelerations within 10 min interval). Vibroacoustic stimulation, thus reduces the rate of falsely worrisome NSTs and therefore adds to the specificity of the NST.

**Fetal biophysical profile** It consists of five components—the NST, fetal movements of flexion and extension, fetal breathing movements, fetal tone, and amniotic fluid volume (AFV). It is performed at 32–34 weeks of gestation for at risk pregnancies over a 30-min period and the presence of each component is assigned a score of two points for a maximum of 10 of 10. A modified biophysical profile refers to an NST and an amniotic fluid index.

A normal score is considered to be 8 of 10 with a nonreactive NST or 8 of 8 without the NST. Equivocal is 6 of 10 and abnormal is less than and equal to 4 of 10. This test assesses the presence of acute hypoxia (changes in the NST, fetal breathing, and body movements) and chronic hypoxia (decreased AFV). A normal fetal biophysical profile appears to indicate intact central nervous system (CNS) mechanisms, whereas factors depressing the fetal CNS reduce or abolish fetal activities. Thus, hypoxemia decreases fetal breathing and, with acidemia, reduces body movements. The biophysical profile offers a broader approach to fetal well-being than does the NST still allowing for a noninvasive, easily learned and performed method for predicting fetal compromise.

## Intrapartum Risk Factors

### Fetal Heart Rate Patterns

Fetal heart rate patterns reflect states of hypoxemia and subsequent acidosis in the fetus. The two common ways of FHR monitoring are cardiotocography and intermittent auscultation. **Cardiotocography** involves continuous monitoring via an electronic machine generating a print out of FHR and uterine contraction over a period of time. **Intermittent auscultation** of fetal heart sounds is usually done by a trained personal using stethoscope, handheld Doppler ultrasound device or by using a Pinard (special trumpet shaped device) over the mother's

abdomen. Reviews comparing the two methods do not find any significant difference of one over the other except that there was higher risk (20% more risk) of operative interventions in the electronic monitoring group as compared to intermittent auscultation in low-risk pregnancies. To be considered reassuring, a cardiotocograph tracing must have the following components:

- A baseline FHR of 110–160 bpm
- Absence of late or variable FHR decelerations
- Moderate FHR variability
- Age-appropriate FHR accelerations (two accelerations in 20 min of 15 beats above the baseline for 15 sec for  $\geq 32$  weeks' gestation, and 2 of 10 beats above the baseline for 10 sec for  $< 32$  weeks' gestation).

The FHR is interpreted with a three-tiered system as follows (**Figures 2A to D**):

- **Category I** (predictive of normal acid base status at that point of time): All of the following criteria must be present and if present, are predictive of normal acid-base status at that point of time:
  - Baseline heart rate: 110–160 bpm
  - Moderate variability
  - Absent late or variable decelerations
  - Present or absent early decelerations
  - Present or absent accelerations
- **Category II** (indeterminate): Includes all FHR's that are neither Category I nor Category III.
- **Category III** (predictive of abnormal acid-base status at the point of observation): These tracings are predictive of abnormal fetal acid-base status at the time of observation and need to be promptly evaluated. These include either of the following:
  - Absent baseline FHR variability and any of the following: recurrent late decelerations, recurrent variable decelerations, or bradycardia.
  - Sinusoidal pattern.

### Fetal Scalp pH

An intrapartum scalp pH above 7.20 with a base deficit less than 6 mmol/L is reassuring of fetal well-being.

**Digital stimulation of fetal scalp** Acceleration of FHR (15 bpm for 15 sec) from the baseline heart rate pattern in response to digital stimulation of fetal scalp in absence of uterine stimulation is a fairly reliable evidence of absence of fetal acidosis ( $\text{pH} > 7.2$ ) and is an alternative to fetal scalp pH determination.

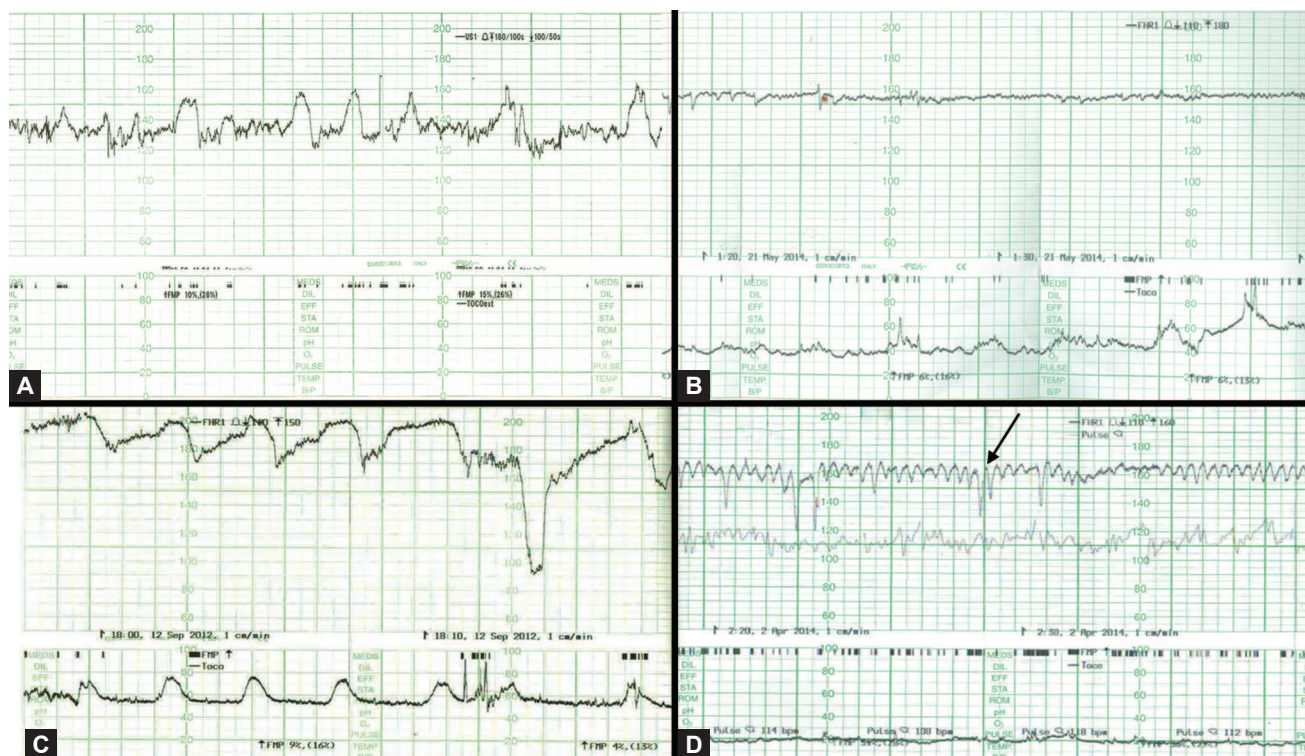

## Postnatal Risk Groups

Disorders of weight and gestation can be identified by the birth weight and gestational assessment soon after birth. Gestational age assessment can be done postnatally using the gestational assessment scales (New Ballards Score and Dubowitz scale) or based on the vascularity of lens using direct ophthalmoscopy. Postnatally, high-risk newborns can be identified at three important stages of examination (**Table 3**):

**Features suggestive of failed transition from intrauterine to extrauterine life** can be diagnosed soon after birth. A failed transition from fetal to newborn status may be due to inability to clear fetal lung fluid, decreased surfactant synthesis, inadequate functional residual capacity, elevated pulmonary vascular resistance, failure to increase systemic blood pressure after removal of the low-resistance placenta from the systemic circuit, persistence of fetal circulation and failure of shunt closure (ductus arteriosus and foramen ovale), or decreased pulmonary blood flow.

**Common congenital anomalies or signs and symptoms suggestive of birth injuries** could be identified after birth, after stabilization of cardiorespiratory status. Presence of *choanal*

**Figures 2A to D** (A) Category I CTG showing baseline FHR 130 bpm with moderate variability and frequent accelerations; (B) Category II CTG showing base FHR around 150–160 bpm with reduced variability with absence of accelerations and decelerations; (C) Category III CTG showing baseline FHR of 160–170 bpm with absent variability and recurrent late decelerations; (D) Category III CTG showing baseline FHR of 160–170 bpm for one of the twins (upper trace: arrow) and sinusoidal pattern

*atresia*, *trachea esophageal fistula* and upper gastrointestinal obstruction can be diagnosed by passing a nasogastric tube in presence of high-risk antenatal risk factors like polyhydramnios and sonographic abnormalities of gastric air (absent stomach bubble or double bubble sign). Inability to pass the nasogastric tube down the esophagus and presence of frothing may provide a clue to presence of tracheoesophageal fistula. The cyanosis with bilateral choanal atresia improves with crying. Baby presenting with apnea or respiratory distress soon after birth with scaphoid abdomen and right-sided heart sounds points toward the left sided congenital diaphragmatic hernia. Aspiration of more than 15–20 mL of gastric aspirate may be suggestive of *duodenal or upper gastrointestinal obstruction*. Palpable bladder with enlarged bilateral kidneys in a male baby points toward *posterior urethral valve*. *Developmental dysplasia of hip* in high-risk babies can be evaluated using Ortolani and Barlow test.

Neonatal morbidities like neonatal jaundice, infection, and manifestation of systemic diseases can be identified by detailed examination done within 24 hours of life and routine (daily) examination until discharge. Routine screening of well babies in the postnatal ward should include anthropometry, hearing screen, examination of red reflex, pulse oximetry screening and newborn screen for metabolic disorders (e.g., hypothyroidism, congenital adrenal hyperplasia, glucose-6-phosphate dehydrogenase deficiency, inborn errors of metabolism). Routine pulse oximetry screening after 24 hours of life (lower limb saturation < 95%) was noted to diagnose critical congenital heart disease with estimated sensitivity of 69.6%, and positive predictive value of 47.0% in a pooled study analysis.

### IN A NUTSHELL

1. Early recognition of high-risk antenatal, natal and postnatal factors will help identify these high-risk newborns which will then allow for early intervention.
2. Antenatal assessment includes gestational age assessment, ultrasonography, serum markers and assessment of fetal well-being using NST, CST, AST and biophysical profile.
3. During labor, the fetus must be closely monitored using the FHR patterns, scalp pH and FHR response to digital scalp stimulation.
4. Soon after birth, the baby is assessed to see if cardiorespiratory transition has been achieved. Subsequently, examination will help identify various congenital malformations/birth injuries and other neonatal morbidities.
5. Routine metabolic screen, universal hearing screen, and pulse oximetry screen are recent tools that are increasingly being used to identify high-risk babies before the onset of disease.

## Chapter 14.2

# Birth Injuries

Neeraj Gupta

Injuries that are sustained during the process of birth (labor and delivery) are known as birth injuries. It also includes injuries related to intrapartum fetal monitoring. However, injuries sustained during amniocentesis, intrauterine transfusion or post-resuscitation is not included. Though there has been a reduction in the incidence of birth injuries with improved obstetric care, they still remain a significant cause of neonatal morbidity. Although many injuries are mild and self-limited, others are serious and potentially lethal. The knowledge about these injuries will help in their timely detection and early management, thus preventing physical and neurodevelopmental handicap. Moreover, the information about various predisposing risk factors may lead to their prevention.

Birth injuries are primarily of two types: those related to physical trauma during the process of birth (traumatic birth injuries) and those due to lack of oxygen (hypoxic-ischemic injury). Both these types of injuries can occur in isolation or in combination. This chapter focuses on the traumatic birth injuries. **Box 1** shows a comprehensive list of traumatic birth injuries highlighting the wide spectrum ranging from minor problems to severe injuries.

### EPIDEMIOLOGY

Birth injuries complicate around 2% of singleton vaginal deliveries and 1.1% of cesarean deliveries in developed world. According to National Neonatal-Perinatal Database 2002–2003, the reported incidence of birth injuries in India was 0.8% and 2.3% in intramural and extramural newborns respectively.

### ETIOLOGY

Various risk factors have been implicated in the causation of birth injuries. Discrepancy between fetal size (macrosomia, cephalopelvic disproportion and shoulder dystocia) or presentation (breech, face, brow and transverse) in relation to birth canal, presence of rigid pelvis (primiparous and old multiparous) or pelvic anomalies and the use of instruments (forceps and vacuum) are the usual factors resulting in majority of these injuries. Prematurity, prolonged labor and precipitous delivery are other risk factors. Cesarean section does not completely eliminate the risk; however, it is less as compared to vaginal delivery. In some cases the risk factors are not identifiable, making these injuries completely unpredictable and unavoidable.

### EVALUATION

Most of these injuries are detected immediately after birth or within first day of life. However, few of them [e.g., congenital muscular torticollis, subcutaneous fat necrosis (SFN)] are picked up late. A complete head to toe examination supplemented with detailed neurological examination primarily focusing on sensorium, symmetry of structure and function and complete range of motion rules out most of them.

### TYPES OF BIRTH TRAUMA

#### Soft Tissue Injuries

##### *Erythema, Abrasions and Lacerations*

These occur in the setting of forceps delivery or dystocia and are present at the site of instrument application or on presenting part

### BOX 1 Traumatic birth injuries

#### *Soft tissue injuries*

- Erythema, abrasions, lacerations
- Petechiae and ecchymosis
- Subcutaneous fat necrosis

#### *Head and neck injuries*

- Extracranial injuries
  - Scalp bruises and laceration
  - Chignon
  - Caput succedaneum
  - Cephalhematoma
  - Subgaleal hemorrhage
  - Skull fractures
- Intracranial injuries
  - Epidural hemorrhage
  - Subdural hemorrhage
  - Subarachnoid hemorrhage
  - Intraparenchymal hemorrhage
  - Intraventricular hemorrhage
  - Cortical contusion, diffuse axonal injury
- Sternocleidomastoid muscle injury

#### *Injuries to face*

- Facial fractures
  - Fractures and dislocations of facial bones
- Nasal injuries
  - Nasal septal dislocation
  - Nasal bone fracture
- Ocular injuries
  - Subconjunctival hemorrhage
  - External ocular muscles
  - Optic nerve
  - Retinal hemorrhage
- Ear injuries
  - Abrasion, lacerations and ecchymoses
  - Hematoma

#### *Nerve injuries*

- Facial nerve palsy
- Recurrent laryngeal nerve injury
- Spinal cord injury
- Phrenic nerve injury
- Brachial plexus injuries
  - Erb's palsy
  - Klumpke's paralysis
  - Total brachial plexus injury

#### *Bone injuries*

- Fracture of clavicle, ribs, humerus, femur
- Epiphyseal separation

#### *Intra-abdominal injuries*

- Rupture of liver
- Rupture of spleen
- Injury to adrenal gland

#### *Injuries related to intrapartum fetal monitoring*

- Injuries related to direct fetal heart rate monitoring
- Injuries related to fetal scalp blood sampling

respectively. These lesions resolve spontaneously and nothing needs to be done except maintaining local hygiene to prevent secondary infection. Lacerations may result following cesarean section. Superficial lacerations just require apposition of the margins with adhesive strips whereas the deeper ones require suturing.

#### *Petechiae and Ecchymosis*

They are commonly associated with breech delivery and tight nuchal cord. Early appearance, localized distribution, absence of bleeding from any other sites and no appearance of new lesions help in differentiating them from thrombocytopenia or

any other bleeding disorder. No treatment is required and they usually disappear within first week of life. Extensive ecchymosis may rarely result in significant hyperbilirubinemia necessitating phototherapy. Very rarely, the blood loss may be severe enough to cause anemia and shock.

### Subcutaneous Fat Necrosis

Subcutaneous fat necrosis of the newborn is an uncommon, transient, self-healing disorder of the adipose tissue that occurs primarily in term or post-term newborns. The exact cause is uncertain however, it is assumed to be due to ischemic injury under various circumstances such as meconium aspiration, birth asphyxia and trauma. SFN is characterized by indurated, erythematous to violaceous nodules and plaques on the back, arms, buttocks, thighs and cheeks (**Fig. 1**). Lesions generally vary in size from 1 cm to 10 cm. This condition is not recognized at birth unlike other birth injuries and usually presents during the first two weeks of life. This condition must be differentiated from sclerema neonatorum and cellulitis because prognosis is largely excellent and no active therapy is required. The lesions resolve spontaneously. The potential complications include hypercalcemia, hypertriglyceridemia, hypoglycemia and thrombocytopenia.

**Figure 1** Erythematous plaques over back and upper arms

## Head and Neck Injuries

### Extracranial Injuries

**Chignon** It is a temporary swelling over scalp after vacuum extraction. It occurs due to the vacuum force which draws the fetal scalp into the body of the cup resulting in characteristic mound of scalp tissue and edema. It is most prominent immediately after the removal of cup and typically resolves spontaneously within next 12–18 hours. No treatment is required.

**Caput succedaneum** It is a vaguely demarcated edematous swelling of the scalp above periosteum (**Fig. 2**) and is occasionally hemorrhagic. It is located over the presenting part during a vertex delivery and occurs after prolonged engagement of the fetal head or after vacuum extraction. It is present since birth and subsides in first 24–48 hours in contrast to cephalhematoma which appears later during the first 24 hours, does not cross midline and is limited by periosteal attachments. Occasionally it may be complicated by secondary infection and necrosis resulting in long-term scarring and alopecia.

**Cephalhematoma** It is a subperiosteal collection of blood (**Fig. 2**) that presents as well demarcated localized swelling over scalp with normal overlying skin. It commonly occurs over parietal bones (**Fig. 3**) and less often involves the occipital or frontal bones. It occurs due to the rupture blood vessels that traverse from skull to periosteum and does not cross suture lines due to the sharp limitation by periosteal attachments. It complicates 1–2% of deliveries and is more common with forceps use or vacuum extraction. The swelling is usually not apparent at birth due to slow subperiosteal bleeding and gradually develops over next 24 hours of life. It may be fluctuant and often the boundary is felt as slightly elevated ridge giving false sensation of central bony depression. Majority of the cephalhematomas resolves spontaneously over next few weeks. However, calcification of the hematoma can result in subsequent bony swelling which may persist for months together. Associated skull fracture may be present in 5–20% cases.

No treatment is required for uncomplicated cephalhematoma. Aspiration or incision is contraindicated due to the risk of secondary infection. Massive cephalhematoma may result in severe blood loss and significant hyperbilirubinemia necessitating appropriate treatment. Other complications include focal infection which may need surgical drainage and parenteral antibiotics as treatment.

**Subgaleal hemorrhage** It is a collection of blood between the periosteum of the skull and the galea aponeurotica (**Fig. 2**). This subgaleal space is a potential space which extends from the orbital

**Figure 2** Diagram depicting various layers of the scalp and their relationship to various hemorrhages

**Figure 3** Bilateral cephalhematoma in a 5 days old term male infant born by spontaneous vaginal delivery

ridges anteriorly to the nape of the neck posteriorly and to the level of the ears laterally resulting in accumulation of blood across the entire calvarium. Subgaleal hemorrhage occurs because of the traction on the scalp during deliveries which result in injury to the bridging veins between the scalp and dural venous sinuses. Risk factors include vacuum and forceps deliveries. It presents as a diffuse fluctuant swelling over the scalp. Progressive accumulation of blood may result in anterior displacement of ears and periorbital swelling along with pallor, hypotonia and shock. Early recognition and intense monitoring including serial hematocrit monitoring is crucial as the massive blood loss may result in high mortality (up to 25%). Treatment includes volume replacement with saline and packed red blood cells along with supportive care. Coagulopathy, if present, needs to be corrected. Phototherapy may be required for hyperbilirubinemia. Surgical drainage is occasionally required in case of unremitting clinical deterioration.

**Skull fractures** These may be linear or depressed and occur due to forceps application or forceful contact of the fetal skull against the maternal bony pelvis or uterine myoma during prolonged and difficult labor.

**Linear fractures** usually affect parietal bones and are often asymptomatic unless associated with intracranial hemorrhage (ICH). They are often associated with cephalhematoma. Uncomplicated linear fractures do not require any therapy and heal without any sequelae. Occasionally a linear fracture may be associated with dural tear leading to herniation of leptomeninges and brain parenchyma resulting in formation of leptomeningeal cyst. Rapid growth of the head may point towards the development of leptomeningeal cyst. Repeat skull radiographs within 8–12 weeks to detect early widening of the fracture line may help in picking up this complication at an early stage resulting in timely excision.

**Depressed fractures** usually involve parietal or frontal bones and appear as visible and palpable indentations in the skull. They are due to inward buckling of the resilient calvarial bones resulting in *ping pong* deformity without any discontinuity. They are also often asymptomatic unless associated with ICH. Skull radiograph shows inward buckling of bone. Cranial CT scan may be needed in symptomatic infants to detect associated intracranial injury. Asymptomatic fractures need no treatment, while symptomatic ones may need surgical intervention.

**Fracture at the base of skull** causes separation of the basal and squamous portions of the occipital bone resulting in severe hemorrhage and cerebral contusion. It occurs during breech

delivery and infant presents with shock, neurological abnormalities and leakage of cerebrospinal fluid from nose or ears. Supportive measures, blood replacement, antibiotics to prevent secondary infection of meninges and immediate neurosurgical intervention are required for successful outcome.

### *Intracranial Injuries*

The prevalence of symptomatic ICH in term infants is around 5.1–5.9 per 10,000 live births. Risk factors include macrosomia, nonvertex presentation, difficult instrumental delivery and bleeding diathesis. Most infants are symptomatic within first 24–48 hours after birth and present with neurological symptoms including seizure and apnea.

**Epidural/extradural hemorrhage** Epidural hemorrhage is very rare and occurs due to the injury to middle meningeal artery. The blood collects between the dura and inner table of the skull (**Fig. 2**). Infant can deteriorate quickly because of the arterial source of bleeding. Approximately half of the cases are associated with large cephalhematoma or linear skull fracture. Cranial CT establishes the diagnosis. Most patients require surgical drainage and prognosis is good except when associated with other ICH or brain injury.

**Subdural hemorrhage** Subdural hemorrhage (SDH) is the most common traumatic ICH in newborns with a prevalence of 2.9–10 per 1,000 live births. It is caused due to the rupture of draining veins and sinuses present in the subdural space. Forces during delivery may cause laceration of the tentorium cerebelli resulting in rupture of various sinuses including straight sinus, vein of Galen transverse sinus or occipital sinus resulting in infratentorial SDH. Supratentorial SDH is caused either due to the laceration of the falx cerebri resulting in rupture of inferior sagittal sinus or superficial veins present over the cerebral convexity. Clinical presentation depends upon the site and amount of blood accumulated. Infants with infratentorial SDH are more likely to present with features of raised intracranial pressure and can deteriorate very rapidly. Cranial CT confirms the diagnosis. Management is supportive and includes volume replacement, and treatment of seizures. Most infants do not require surgical intervention however, large SDH with features suggestive of brainstem compression or rapid neurological deterioration require prompt surgical drainage. Bleeding diathesis should be ruled out in large SDH. Prognosis is generally good however, depends upon the size of SDH along with any associated brain parenchymal injury. The potential complications include obstructive hydrocephalus and chronic subdural effusion.

**Subarachnoid hemorrhage** Subarachnoid hemorrhage (SAH) is caused due to the rupture of the bridging veins of the subarachnoid space or small leptomeningeal vessels. The most common symptom is seizures that often occur on the second day of life. Cranial CT confirms the diagnosis; however, MRI brain is more useful to determine coexisting ICH and other parenchymal pathology. Management is supportive and prognosis is good unless complicated by cortical or hypoxic injury. Occasionally, posthemorrhagic hydrocephalus may develop in large SAH warranting serial monitoring of head circumference and cranial ultrasonography to look for increasing ventricular size.

**Intraparenchymal hemorrhage** Primary traumatic intraparenchymal hemorrhage is uncommon in newborns and is more often due to the rupture of an aneurysm or coagulation disturbance. Cranial CT or MRI confirms IPH along with other associated cranial injuries. Management is largely supportive. Prognosis depends upon the location and size of the IPH along with gestational age of the infant.

### *Sternocleidomastoid Muscle Injury*

Injury to sternocleidomastoid muscle (SCM) results from abnormal pressure or trauma to the SCM during intrauterine or perinatal period resulting in hematoma and subsequent fibrosis and shortening. Most infants present during second and third week of life with a well circumscribed hard palpable mass of about 1–2 cm diameter in the middle part of SCM. Treatment includes active and passive stretching of the muscle several times a day to prevent torticollis. Most patients improve within 3–4 months.

## INJURIES TO FACE

### Facial Fractures

Facial fractures may occur due to delivery by forceps or during breech deliveries. The usual bones which are involved are maxilla, mandible and the lacrimal bones. Infants present with facial asymmetry along with edema, ecchymoses and crepitus. There may be associated respiratory distress with poor feeding. Appropriate radiograph confirms the diagnosis and cranial CT or MRI may be required to evaluate retro-orbital or cribriform plate disruption. Airway should be maintained and treatment should begin immediately in consultation with plastic surgeon, dental surgeon and otorhinolaryngologist. Prompt treatment is required because lacrimal and maxillary fractures begin to heal within 7–10 days and mandibular fractures within 10–14 days. Untreated fractures can lead to facial deformities, malocclusion and subsequent mastication problems.

### Nasal Injuries

The most common nasal injury is dislocation of the cartilaginous part of the nasal septum from the vomerine groove with a reported prevalence of 0.6–0.9% of all deliveries. The other injuries include fracture of the nasal bone, edema of the nasal passage and misshapen nose. All these injuries are caused due to the compressive forces during delivery. Infants may develop respiratory distress and cyanosis and examination may reveal deviation of the nose to one side. Septal dislocation can be differentiated from the more commonly occurring misshapen nose by a simple compression test. Application of pressure on the tip of the nose causes collapse of the nostril and the deviated nasal septum to become more prominent whereas no nasal deviation occurs in a misshapen nose. Nasal septal dislocation must be reduced within 3 days by an otorhinolaryngologist as untreated dislocations may result in increased risk of long-term septal and cosmetic deformity. Nasal fractures must also be treated promptly like facial bone fractures as they begin to heal within 7–10 days after injury.

### Ocular Injuries

Subconjunctival and retinal hemorrhages are common after vaginal deliveries and results from increased venous congestion during the process of birth. However, these lesions usually resolve spontaneously within 1–2 weeks and do not require any specific treatment. Other significant ocular injuries include lid lacerations, orbital fracture, lacrimal gland and duct injury, rupture of Descemet's membrane of the cornea (resulting in clouding of cornea and must be differentiated from congenital glaucoma), corneal abrasion, hyphema (blood in the anterior chamber), vitreous hemorrhage, optic nerve injury and injury to external ocular muscles. These injuries are caused due to inappropriate forceps placement, abnormal presentation or rarely due to displacement of fetal monitoring electrodes. Prompt evaluation and management by an ophthalmologist is required to prevent permanent damage.

### Ear Injuries

Ears get injured either during forceps delivery or due to fetal malposition. Superficial lacerations of the pinna may be sutured by a pediatrician. However, if cartilage is involved then otorhinolaryngologist should be consulted because of the risk of perichondritis and subsequent ear deformities. Hematoma of the pinna should be drained promptly because of its tendency to organize early leading to the formation of cauliflower ear. Temporal bone injury can cause middle and inner ear complications including hemotympanum and ossicular disarticulation.

## NERVE INJURIES

### Facial Nerve Injury

It is the most common peripheral nerve injury in neonates and occurs in 0.1–0.7% of live births. Prolonged pressure from the sacral promontory during intrauterine period or application of forceps during delivery causes compression of the peripheral portion of the nerve as it exits through the stylomastoid foramen or runs over the ramus of mandible resulting in facial nerve palsy. Though the paralysis is present since birth, it is usually detected on the first or second day of life. In peripheral injury, the entire side of the face is involved with affected side of the face being expressionless, absence of wrinkles over the forehead and flat nasolabial fold. Infant is unable to close the ipsilateral eyelid completely and the angle of the mouth deviates towards the unaffected side while crying. If only one of the peripheral branches of the facial nerve is involved then the paralysis is limited to the focal group of facial muscle namely forehead, eyelid or mouth. In central facial nerve palsy, paralysis is limited to lower two-thirds of the contralateral side of the face. Movement of the forehead and eyelid is preserved. Traumatic facial nerve injury needs to be differentiated from developmental or syndromic etiologies and congenital hypoplasia of depressor anguli oris muscle.

Treatment involves protection of the involved eye by patching and using artificial tears to prevent corneal injury. Most patients recover spontaneously within first 2 weeks of life. Surgical intervention is considered only after lack of resolution during 1 year of observation. In patients with no evidence of recovery, electrodiagnostic studies may be useful to predict prognosis.

### Recurrent Laryngeal Nerve Injury

It is caused due to excessive traction on the fetal head during breech delivery or after forceps application. The left nerve is more commonly involved than right one due to its longer course. Bilateral involvement is more common due to hypoxia or brainstem hemorrhage rather than trauma. Infants with unilateral involvement are often asymptomatic at rest but may develop inspiratory stridor, respiratory distress and hoarseness while crying. Bilateral involvement invariably presents with severe respiratory distress and cyanosis. Differential diagnosis of unilateral involvement includes laryngeal malformations. Unilateral involvement usually recovers spontaneously within 6 weeks. Frequent and small feeds may be required to decrease the risk of aspiration. Intubation may be required in cases of persistent respiratory distress. Bilateral involvement is usually severe and often requires intubation to support airway.

### Spinal Cord Injury

Spinal cord injuries are rare but catastrophic. These occur due to excessive longitudinal traction or rotation of the spinal cord during mid-forceps application or difficult breech extraction. The various spinal injuries include epidural hematoma, vertebral artery injuries, hematomyelia, spinal artery occlusion, and transection of the spinal cord. High cervical or brainstem injury often results

in stillbirth. Surviving infants may be in poor condition with respiratory failure and shock. Infants with upper or mid-cervical cord injury present with respiratory depression and apnea. The extremities are flaccid with absent deep tendon reflexes. There may be associated urinary retention and patulous anus. Injury to lower cervical and thoracic cord may be partly reversible but with long-term neurological sequelae. Differential diagnosis includes intracranial injury, congenital hypotonia, myelodysplasia associated with spina bifida occulta and neuromuscular diseases.

Ultrasonography is the diagnostic method of choice however; the initial suspicion of spinal injury may get delayed because of associated hypoxic-ischemic encephalopathy which clouds the clinical picture. Magnetic resonance imaging provides better visualization of the spinal cord and is the preferred modality. Treatment is supportive and involves neurosurgeons. If cord injury is suspected at the time of birth, the head, neck and spine should be immobilized. In general, the prognosis is poor and depends on the severity and the location of the spinal injury.

### Phrenic Nerve Injury

Phrenic nerve (nerve root- C3, C4 and C5) usually gets injured due to the hyperextension of the neck during breech or difficult forceps delivery. Most of the cases have unilateral involvement and three-fourth of the cases have associated brachial plexus injury. The infant may present with respiratory distress and cyanosis. Examination reveals decreased movement of the ipsilateral hemithorax and paradoxical breathing. Chest radiograph shows the elevation of diaphragm on the affected side. Initial treatment is supportive and includes airway care to prevent atelectasis and pneumonia. Ventilation may be required to support respiratory distress. Most patients recover in 1–3 months without any sequelae. Refractory cases require surgical plication of diaphragm.

### Brachial Plexus Injury

Brachial plexus injury is not uncommon with a prevalence of around 0.1–0.2% of all the births. It is caused due to the excessive traction on the cervical nerve roots during delivery. The potential risk factors include macrosomia, shoulder dystocia, difficult delivery, breech extraction and instrumental deliveries. Injury to the brachial plexus results in paralysis of the upper extremity. It manifests in three different forms depending on the nerve roots involved:

- **Erb-Duchenne (Erb's) palsy:** It is the most common form of brachial plexus injury and accounts for 90% of the cases. It results from injury to the C5 and C6 nerve roots of the upper trunk and occasionally involves C7. The upper limb is typically adducted and internally rotated at the shoulder joint, extended and pronated at the elbow joint with flexion of the wrist and fingers resulting in characteristic *waiter's tip* posture (**Fig. 4**). Moro's and biceps reflexes are absent, but grasp reflex is preserved. Phrenic nerve may also be injured in around 5% cases.
- **Klumpke's paralysis:** It results from injury to the C8 and T1 nerve roots and accounts for less than 1% of all the brachial plexus injuries. It involves intrinsic muscles of the hand and long flexors of the wrist and fingers. Grasp reflex is typically absent however biceps and radial reflexes are intact. There may be associated features of ipsilateral Horner syndrome (ptosis, miosis and enophthalmos) due to the involvement of sympathetic fibers which are embedded in T1 nerve root.
- **Total brachial plexus injury:** It involves all the nerve roots from C5 to T1 and accounts for 10% of the cases. The entire upper limb is flaccid with loss of all the reflexes (including grasp reflex) and absence of sensation.

**Figure 4** Waiter's tip posture of the right arm in Erb's palsy. Note the characteristic posture involving adduction and internal rotation at shoulder, extension at elbow, pronation of forearm and flexion of wrist and fingers

Reproduced with permission: From Chauhan SP, Yang LJ. Neonatal brachial plexus palsy—management and prognostic factors. *Semin Perinatol.* 2014;38:222–34. Copyright © 2014 Elsevier Inc.

Initial management is conservative and involves physical therapy involving passive range of motion exercises at all the joints to prevent contractures. This should be started after first week of life once the postinjury neuritis gets resolved. Prognosis depends upon the severity of nerve injury which ranges from neurapraxia (with rapid recovery) to nerve root avulsions (with no spontaneous recovery). Most (50–80%) infants recover spontaneously by 3 months of age. Infants with no recovery by 3–6 months of age are candidates for surgical intervention.

## BONE INJURIES

### Clavicular Fracture

It has been reported in up to 3% of the neonates. Most clavicular fractures occur during normal spontaneous vaginal delivery, however, the incidence increases in the presence of shoulder dystocia, macrosomia and breech delivery. Clavicular fracture may be complete or incomplete (greenstick). Incomplete fractures are usually asymptomatic at birth and are first detected after the appearance of an obvious swelling (callus) in the supraclavicular fossa during second week of life. Up to 40% of the clavicular fractures are not identified until after discharge from the hospital. The most common symptom at birth includes decreased movement of the ipsilateral arm. Examination may reveal crepitus, a palpable bony abnormality, obliteration of the supraclavicular depression due to the spasm of SCM and an asymmetric Moro's reflex. Diagnosis is confirmed by a radiograph (**Fig. 5**) which also helps in ruling out the humeral fracture. Treatment involves analgesics and immobilization of the arm. Recovery is complete without any sequelae.

### Fracture of the Humerus

It is the most common long bone which gets fractured at the time of birth. It typically occurs during difficult delivery of the extended arms in breech presentation and shoulders in the vertex presentation. Other risk factors include shoulder dystocia, macrosomia, cesarean delivery and low birth weight. Most fractures occur at the proximal third of the humerus. The first symptom is

**Figure 5** A full-term newborn via spontaneous vaginal delivery. Note the right clavicle fracture in the distal one-third in this newborn with meconium aspiration

*Reproduced with permission:* From Huisman TAGM, Hillenbrand CM, Tekes A, Pinto PS, Huisman TA. Birth-related injury to the head and cervical spine in neonates. *Magn Reson Imaging Clin N Am.* 2011;19:777-90. Copyright © 2011 Elsevier Inc.

decreased or absent movement of the involved limb. There may be associated localized swelling, deformity, crepitation, and increased pain with the movement of the involved limb. Moro's reflex may be sluggish or absent on the involved side. Greenstick fracture may be overlooked until a callus is noted. Diagnosis is confirmed by a radiograph. Treatment involves reduction of the displaced fracture followed by splinting for 2–4 weeks in an adducted position. Radial nerve injury may be associated with humeral fracture.

### Fracture of the Femur

It is the most common fracture of the lower extremity and involves the proximal half of femur. Risk factor includes breech delivery or cesarean section. Newborns with congenital hypotonia are also prone. Examination reveals an obvious deformity of the thigh along with decreased movements. Diagnosis is confirmed on radiograph. Treatment involves traction and suspension of both legs in a spica cast or Pavlik harness even if the fracture is unilateral. Prognosis is excellent.

### Epiphyseal Separation

These are rare injuries and occur due to the vigorous pulling of an extremity at the time of birth. The upper femoral and humeral epiphyses are most often involved and get separated from the underlying metaphysis. It is important to differentiate epiphyseal separation from the dislocations as the management differs. Dislocations especially of the hip and knee joints are due to intrauterine positions rather than trauma at the time of birth. Decreased movement of the involved extremity along with swelling and tenderness of the overlying soft tissue is the usual presentation in epiphyseal plate separation unlike dislocations. Diagnosis is confirmed on ultrasonography because epiphysis is not ossified at birth. Treatment involves immobilization for 10–14 days. Severe displacements may result in significant growth disturbance and permanent deformity of the involved extremity later on in the life.

### Fracture of the Ribs

These are extremely rare and occur when the anterior shoulder is impacted behind the symphysis pubis and the other shoulder tries to descend resulting in compression of the fetal thorax. These are usually asymptomatic and are detected when a chest radiograph is done for other reasons including suspected clavicular fracture or respiratory distress. No specific treatment is required and recovery is excellent.

### INTRA-ABDOMINAL INJURIES

Intra-abdominal injuries are rare and may involve liver, spleen, kidneys and adrenal gland. These injuries occur as a result of direct trauma, compression of the chest against solid organs or tearing of ligamentous insertion of liver and spleen during delivery. Ultrasonography is the best bedside modality to diagnose these injuries; however CT may be required in selective cases. Management includes restoration of blood volume and correction of underlying coagulopathy. Laparotomy is required in refractory cases who do not improve on conservative management.

### Hepatic Injury

Liver is the most frequently injured intra-abdominal organ. Injury varies from asymptomatic subcapsular hematoma and laceration to complete rupture resulting in rapid death. Subcapsular hematoma may present with nonspecific signs of blood loss including pallor, tachycardia, tachypnea, pathological jaundice and poor feeding. A mass may be palpable in the right upper quadrant of the abdomen. Serial hematocrits may suggest blood loss. Rupture of the enlarging subcapsular hematoma causes circulatory collapse and hemoperitoneum resulting in abdominal distension and discoloration of the overlying abdominal skin.

### Splenic Injury

The presentation is similar to hepatic injury. Occasionally, there may be a palpable mass in left upper quadrant with abdominal radiograph revealing medial displacement of the gastric air bubble.

### Adrenal Injury

The relatively large size along with increased vascularity of the adrenal glands in newborns may contribute to this injury. 90% of adrenal hemorrhages are unilateral and involves the right sided gland. There may be associated features of adrenal insufficiency in form of vomiting, diarrhea, dehydration, hypoglycemia and refractory shock apart from features of blood loss and hemoperitoneum. A flank mass may be palpable and one needs to consider neuroblastoma and Wilms tumor as possible differential diagnosis in such cases. Treatment includes steroid replacement apart from conventional management as in hepatic and splenic injury.

### INJURIES RELATED TO INTRAPARTUM FETAL MONITORING

#### Injuries Related to Direct Fetal Heart Rate Monitoring

Electrodes placed on the fetal scalp or presenting part for fetal heart rate monitoring can cause superficial abrasions or lacerations at the site of placement of an electrode. Occasionally, facial or ocular trauma may result from malpositioned electrode. These injuries require no specific therapy beyond local treatment.

### IN A NUTSHELL

1. Birth injuries constitute an important preventable cause of physical and neurological handicaps.
2. Important risk factors that increase the risk of birth injuries include macrosomia, breech presentation, instrumental vaginal delivery, shoulder dystocia and maternal pelvic anomalies.
3. The most frequent traumatic birth injuries are soft tissue injuries with laceration being the most common injury associated with cesarean section.
4. Most extracranial injuries resolve spontaneously except subgaleal hemorrhage which may result in massive blood loss leading to shock and death. Skull fractures are usually benign except large depressed fractures and fracture involving the base of the skull, both of which may prove fatal.
5. Intracranial injuries include epidural, subdural, subarachnoid, intraparenchymal and intraventricular hemorrhage. The decision for neurosurgical intervention is based upon the clinical condition of the patient including evidence of increased intracranial pressure, and the nature and size of the injury.
6. The most common peripheral nerve injury is facial nerve injury and most patients recover spontaneously within first two weeks of life. Although spinal cord injuries are rare, they generally have a poor prognosis due to high mortality rate and increased chances of permanent neurologic impairment among the survivors.
7. Fractures due to birth trauma may involve ribs, clavicle, humerus and femur. These require immobilization and generally resolve within two to four weeks with excellent long-term prognosis.
8. Intra-abdominal injuries are rare and may involve liver, spleen, kidneys and adrenal gland. Their presentation and management varies depending upon the degree of internal bleeding.

### Injuries Related to Fetal Scalp Blood Sampling

Hemorrhage and breakage of the blade inside the scalp are the known complications associated with fetal scalp blood sampling. Local pressure and occasionally suturing is required to treat hemorrhage. The broken blade inside the fetal scalp needs to be removed soon after delivery to prevent secondary infection.

## Chapter 14.3

# Jaundice in the Newborn

Sheila S Mathai, Kannan Venkatnarayan

Jaundice is the visible manifestation of yellowness of the skin and sclera due to elevated serum bilirubin levels. It is seen in neonates when the serum bilirubin levels exceed 5–7 mg/dL (86–119  $\mu$ mol/L). Jaundice is seen first on the skin rather than the sclera in neonates as the eyes are difficult to examine in a baby. Hyperbilirubinemia typically refers to serum bilirubin levels beyond the normal range. Approximately, 70–80% of babies develop some jaundice during the early neonatal period, due to physiological hyperbilirubinemia. Though this is self-limiting in most cases without treatment, severe hyperbilirubinemia can occur due to various reasons in babies. Bilirubin is neurotoxic in neonates and healthy babies can sometimes sustain irreversible brain damage if hyperbilirubinemia is not managed promptly. Adverse consequences include the classic manifestations of kernicterus, isolated auditory impairment or subtle, processing disturbances.

## EPIDEMIOLOGY

An increased incidence of hyperbilirubinemia is associated with risk factors like racial, genetic, familial, maternal and neonatal factors. In India, a higher incidence is seen in Western, Northwestern and Eastern regions. Reasons for such racial variations are not clear and could include genetic and environmental traits affecting red blood cell (RBC) membrane stability and the prevalence of conditions such as glucose-6-phosphate dehydrogenase (G6PD) deficiency in the community. Recently, the gene for the enzyme responsible for bilirubin conjugation, uridine diphosphate glucuronosyltransferases 1A1 (*UGT1A1*), located on chromosome 2, along with genetic analysis of the *G6PD* genes, have thrown new light on the understanding of racial differences and familial causes of hyperbilirubinemia. Specific mutations affecting the promoter (noncoding) region of the amelogenesis imperfecta (AI) exon of the gene, such as increase in TATA repeats (TATA box mutation), is associated with hyperbilirubinemia in Gilbert syndrome. This mutation in isolation is benign but if associated with mutations in the *G6PD* gene has been found to markedly increase the risk for hyperbilirubinemia in Indian neonates. The Crigler-Najjar syndromes are usually caused by one or more mutations in any of the five exons of the *UGT1A1* gene that result in almost absence of the conjugating enzyme activity (Type 1) or severely reduced but phenobarbital-inducible enzyme activity (Type 2).

## BILIRUBIN METABOLISM

Bilirubin is the by-product of heme break down, 75% of which is generated from RBC and the rest from ineffective erythropoiesis, tissue heme and other heme proteins. The heme is oxidized to biliverdin in the reticuloendothelial system by heme oxygenase and subsequently reduced to bilirubin by biliverdin reductase. The former reaction results in release of carbon monoxide (CO) and iron (which is reutilized). Catabolism of one mole of hemoglobin results in the production of one mole each of CO and bilirubin. Bilirubin, in the unconjugated form, is nonpolar and insoluble in water but very lipophilic. In physiological quantities, it is a natural antioxidant and the so-called physiological hyperbilirubinemia of the newborn may actually have undocumented benefits. It is bound with albumin which prevents it from crossing the blood-brain barrier and entering the central nervous system. Approximately

7–8 mg of bilirubin can bind to 1 g of albumin. Bilirubin exists in the plasma in four forms: unconjugated bilirubin bound to albumin, which forms the major, conjugated bilirubin, which exists in the mono and diglucuronide forms, free, unbound, unconjugated bilirubin and  $\delta$ -fraction which is only found in prolonged states of conjugated hyperbilirubinemia, wherein conjugated bilirubin is covalently bound to albumin. Albumin-bound bilirubin is taken up by hepatocytes and bound to intracellular Y proteins (ligandins) for transportation to the smooth endoplasmic reticulum. Here the unconjugated bilirubin (indirect) is converted to water-soluble, polar, conjugated bilirubin, which is excreted into the biliary canaliculi by active transport. It enters the intestine and is excreted after conversion to stercobilin by gut bacteria. The intestine contains the enzyme  $\beta$ -glucuronidase which can unconjugate bilirubin resulting in it getting reabsorbed and delivered back to liver (enterohepatic circulation of bilirubin). The applied aspects of bilirubin metabolism are mentioned in **Table 1**.

## ETIOLOGY

### Physiological Jaundice

A relatively lower life span of RBCs, increased RBC mass, immature conjugation of bilirubin, with higher levels of monoglucuronide rather than diglucuronide forms, paucity of intestinal bacteria, enhanced  $\beta$ -glucuronidase activity in the gut and decreased motility of intestines, all contribute to the physiological jaundice of the newborn. Typically, this results in total serum bilirubin (TSB) levels of up to 10–14 mg/dL between 72 hours and 120 hours of life followed by a decline to normal by 7–10 days of life. This physiological hyperbilirubinemia is exaggerated in pretermers. Babies with physiological jaundice are essentially well and do not require treatment. Any other pattern of hyperbilirubinemia should be considered pathological unless proved otherwise. Common causes of pathological, unconjugated hyperbilirubinemia are given in **Box 1**. The term exaggerated physiological jaundice is sometimes used to describe a condition wherein the serum bilirubin briefly reaches phototherapy (PT) levels but no definite cause is found and the baby remains well. This may be seen in babies with marginal polycythemia, hidden subcutaneous blood collections or due to unknown reasons.

### Breastmilk and Jaundice

Breastfeeding, compared to formula feeding, is associated with an increased incidence of jaundice. Almost 13% of breastfed babies versus 4% of formula fed babies have TSB levels of 12 mg/dL or higher with 2% having levels exceeding 15 mg/dL. Two separate patterns of jaundice in breastfed infants are described: breastfeeding jaundice and breastmilk jaundice and it is important to distinguish between them (**Table 2**). Current consensus is not to interrupt breastfeeding irrespective of jaundice.

### Hemolytic Disease of Newborn

The most common cause of hemolysis is due to isoimmune hemolytic disease caused by blood group incompatibility between mother and fetus. Rh and ABO isoimmunization are the most common.

### Rh Incompatibility

While Rh hemolytic disease of newborn (Rh-HDN) has almost been eliminated in the developed world due to use of anti-D IgG combined with aggressive fetal surveillance, this disease is still a major burden in developing countries including India. The estimated annual number of Rh-HDN cases occurring in India is approximately 56,700. The Rh-negative mother is sensitized to the Rh antigen present on the fetal RBCs, due to fetomaternal

**Table 1** Applied aspects of bilirubin metabolism

<i>Steps in bilirubin metabolism</i>	<i>Relevance</i>	<i>Application in clinical practice</i>
Heme breakdown results in bilirubin production	Neonates have a high RBC mass and lower life span of RBC than adults (90 versus 120 days) Conditions associated with hemolysis results in high bilirubin load (1 g hemoglobin yields approximately 35 mg of bilirubin)	Partly explains physiological hyperbilirubinemia  Conditions such as G6PD deficiency, Rh isoimmunization, ABO incompatibility, polycythemia and extravascular blood accumulation are considered risk factors for severe hyperbilirubinemia In acute hemolysis, both rate of fall of packed cell volume (PCV) and rate of rise of serum bilirubin considered for need of exchange transfusion
Heme breakdown to biliverdin is mediated by heme oxygenase (HO) and CO is released as by-product	Rate of production of carbon monoxide directly correlates with bilirubin production Blockage of CO activity can lead to reduced production of bilirubin	End tidal carbon dioxide (EtCO <sub>2</sub> ) estimation by breath analyzer has been studied as a novel tool to assess at-risk babies for hyperbilirubinemia Use of metalloporphyrins (tin mesoporphyrin) has been tried as a modality of treatment for neonatal hyperbilirubinemia
Bilirubin is transported by binding to albumin	Bilirubin bound to albumin is safe and does not enter CNS as it cannot cross the blood-brain barrier Preterm have low albumin levels	High rates of bilirubin production saturate the albumin sites, thus decreasing the risk of entry of unbound, unconjugated bilirubin into the brain Unconjugated bilirubin is highly lipophilic and deposits in the brain resulting in tissue injury which may be permanent Risk of neurotoxicity is directly proportional to molar ratio of bilirubin to albumin
Bilirubin is taken-up by hepatocytes	Cytoplasmic protein ligandin (Y protein) transports bilirubin to smooth endoplasmic reticulum (SER)	Phenobarbital induces ligandin protein formation as well as proliferation of SER and hence has a therapeutic role
Unconjugated bilirubin (UCB) is conjugated by UDPGT1A in SER to conjugated bilirubin (CB)	Conjugation is an important step to convert bilirubin into a water-soluble, nontoxic compound	The UDPGT enzyme activity is less in preterm babies and varies with population, depending on its genetic expression
Conjugated bilirubin is excreted in bile by stools. CB can be converted to UCB by intestinal enzyme $\beta$ -glucuronidase, which is then resorbed	Reabsorption of UCB from GI tract and delivery back to liver for reconjugation is called enterohepatic circulation	Conditions causing slow clearance of meconium from intestine (such as pyloric stenosis, hypothyroidism, and intestinal atresias) account for enhanced enterohepatic circulation Breastmilk has significant $\beta$ -glucuronidase activity

*Abbreviations:* GI, gastrointestinal; CO, carbon monoxide; UDPGT, uridine diphosphate glucuronosyltransferase; G6PD, glucose-6-phosphate dehydrogenase; RBC, red blood cell.

hemorrhage which may be as little as 0.1 mL. Major sensitization occurs during delivery. The initial maternal antibody response is IgM which does not cross the placenta, but the later produced IgG antibodies cross the placenta and attach to the fetal Rh antigen-positive cells, making them susceptible to destruction in the reticuloendothelial system. Depending on the degree of destruction, manifestations may range from hydrops fetalis, due to severe anemia and congestive cardiac failure (25%) or rapid rise in bilirubin soon after delivery to no symptoms at all (15–20%). The degree of sensitization in the mother depends on the antigenicity of fetal RBCs, the specific antigen involved (D is more antigenic than C or E Rh-antigens) and the amount of fetomaternal hemorrhage. It is also likely to be more in later pregnancies. Concomitant presence of ABO incompatibility reduces the chances of Rh isoimmunization due to premature destruction of fetal RBCs by maternal ABO system. With the development of fetal anemia, middle cerebral artery peak systolic velocity (MCA-PSV) increases. Measurement of this by antenatal fetal Doppler can determine the severity of the disease, with values more than 1.5 multiples of median (MoM) for gestational age being an indication for in utero blood transfusion. The other means of in utero assessment remains the optical density measures of amniotic fluid for bilirubin with plotting on Liley and Queenan charts.

### **ABO Incompatibility**

This occurs due to maternal anti-A or anti-B antibodies reacting with fetal RBC antigen and typically occurs with maternal O blood group,

as antibodies produced in them are of IgG type whereas other blood group individuals produce IgM antibodies which do not cross the placenta. Though the mechanism of disease is similar to Rh-HDN, the disease due to ABO incompatibility is generally milder and presents later. This is probably due to the ubiquitous nature of AB antigens resulting in a relatively weaker antibody response.

### **Minor Blood Group Incompatibility**

Isoimmunization against Kell, Kidd, Lutheran and other red cell antigens also rarely cause neonatal jaundice. They should be suspected in babies presenting with hyperbilirubinemia and anemia suggestive of hemolysis within the first 24 hours of life with no setting for Rh or ABO incompatibility but with positive direct Coombs test.

### **Red Blood Cell Enzyme Abnormalities**

Glucose-6-phosphate dehydrogenase deficiency is the most common cause in this category and can result in severe hyperbilirubinemia. The disease is widely prevalent in many parts of the world such as Greece, Africa and East Asia. In India, the incidence is high, with 13 different biochemical variants, and ranges from 0% to 27%. It is seen in higher frequency in certain tribals and minority communities. In the absence of G6PD, the pentose phosphate pathway cannot generate nicotinamide adenine dinucleotide phosphate (NADPH), which is an important source of protons that are required for the generation of reduced glutathione, an antioxidant. In G6PD deficiency, RBCs are unable

**BOX 1 Causes of unconjugated hyperbilirubinemia**

- A. *Excessive production of bilirubin*
  1. *Blood group incompatibility*
    - a. Rh isoimmunization
    - b. ABO incompatibility
    - c. Minor blood group incompatibility
  2. *Red blood cell enzyme abnormalities*
    - a. Glucose-6-phosphate dehydrogenase deficiency
    - b. Pyruvate kinase deficiency
  3. *Red blood cell membrane defects*
    - a. Hereditary spherocytosis
    - b. Elliptocytosis
    - c. Poikilocytosis
  4. *Extravascular blood breakdown*
    - a. Cephalhematoma, subgaleal bleed
    - b. Tissue bruising
    - c. Fractures
  5. *Polycythemia*
  6. *Sepsis*
- B. *Impaired conjugation*
  1. *Hormonal deficiency*
    - a. Hypothyroidism
    - b. Hypopituitarism
  2. *Disorders of enzyme/inhibitors of enzyme*
    - a. Crigler-Najjar syndrome type I
    - b. Crigler-Najjar syndrome type II (Arias disease)
    - c. Gilbert disease
    - d. Lucey-Driscoll syndrome
    - e. Breastmilk jaundice
- C. *Enhanced enterohepatic circulation*
  1. Intestinal obstruction, pyloric stenosis
  2. Ileus, meconium plugging, cystic fibrosis
  3. Breastfeeding jaundice

to tackle oxidant stresses such as those induced by sepsis, drugs and chemicals. G6PD enzyme activity is heterogeneous in deficient neonates with five levels of activity: Class I, severe deficiency; II, severe deficiency with 1–10% residual enzyme activity; III, moderate deficiency with 10–60% residual enzyme activity; IV, normal enzyme activity at 60–150%; and V, increased enzyme activity at more than 150%. Hyperbilirubinemia in these neonates is a manifestation of close interaction of various genotypic and phenotypic factors, such as late preterm, sepsis, dehydration, exposure to drugs and TATA box mutations of the *UGT1A1* gene.

**NEUROTOXICITY OF BILIRUBIN**

Unconjugated bilirubin can cross the blood-brain barrier due to many factors. These include alterations in the bilirubin-binding capacity of albumin and other proteins and disruption of the blood-brain barrier due to underlying conditions like asphyxia, meningitis or acidosis. Increased bilirubin production can overwhelm the normal buffering capacity of the blood and result in the production of bilirubin acid, which is highly neurotoxic. Unconjugated bilirubin is toxic to a plethora of neural cells like astrocytes, microglia and oligodendrocytes. It induces apoptosis, necrotic cell death and neurite outgrowth. In addition, its immunostimulant effects lead to the release of proinflammatory cytokines and secondary neuronal damage. The clinical manifestation of bilirubin toxicity is assumed to be due to integrated nerve disturbance. The exact level of TSB at which neuronal damage occurs is still elusive and multiple guidelines have been developed incorporating various risk factors for neurotoxicity. Recent evidence from the follow-up of large, randomized-control studies it has been shown that, in micropreemies, a mean difference of 2.2 mg% of TSB between the intervention and treatment group resulted in significant neurodevelopmental benefit including a reduction in athetosis and severe hearing loss. That this benefit occurred at the cost of increase in mortality in a subgroup of babies (birth weight 501–750 g) underlines the complex nature of bilirubin both as a natural protective antioxidant and an agent of neurotoxicity.

**Clinical Manifestations**

The initial features of bilirubin neurotoxicity are reversible. Brain-stem auditory evoked response (BAER) can show early signs of acute bilirubin encephalopathy with characteristic changes in the wave latency and magnitude. BAER shows significant prolongation of latencies of waves III and IV-V, and interpeak I-III and I-V, suggesting interference in brainstem conduction in neonates with TSB of 10–20 mg/dL (171–342  $\mu$ mol/L). These are reversed rapidly with either an exchange transfusion (ET) or a spontaneous decline in TSB concentrations. Acute bilirubin encephalopathy typically progresses through three stages:

**Stage 1**

It occurs during the first few days, with the infant showing decreased activity, poor suck, hypotonia and a slightly high-pitched cry. If the TSB level is rapidly decreased (by ET) the abnormalities are often reversed.

**Table 2** Distinguishing features between *breastfeeding jaundice* and *breastmilk jaundice*

	<i>Breastfeeding jaundice</i>	<i>Breastmilk jaundice</i>
Clinical presentation	Hyperbilirubinemia with significant weight loss in the first week of life	Persistence or prolongation of apparent physiological jaundice in an otherwise healthy term beyond day 14
History	Multiple issues related to breastfeeding resulting in inadequate feeding with poor stool output	Exclusively breastfed, good lactation, gaining weight well, passing adequate stools History of jaundice in previous siblings
Cause	Increased enterohepatic circulation due to decreased gut motility secondary to infrequent feeding Poor calorie intake interfering with conjugation of bilirubin	Largely unknown. Plausible mechanisms include presence of unknown inhibitory substance in breastmilk that interferes with conjugation of bilirubin (3 $\alpha$ 20 $\beta$ pregnanediol, lipases, and free fatty acids), increased enterohepatic circulation due to excess $\beta$ -glucuronidase in breastmilk and slow colonization of intestine by bacteria
Course	May need phototherapy for a few days. Responds rapidly to measures to ensure adequate breastmilk feeding	Total serum bilirubin (TSB) levels increase till 4–6 weeks and subsequently normalize by 8–12 weeks of age. Maximum TSB may rarely reach 20 mg/dL If breastfeeding is interrupted, the TSB levels rapidly decline and do not rise again to previous high values
Management	Ensure adequate breastfeeding and management of hyperbilirubinemia as per guidelines	Except in rare instance, it is not advisable to stop or interrupt breastfeeding as the potential disadvantages of this outweigh any gains

## Stage 2

It develops a few days later with the infant demonstrating rigid extension of the extremities, tight-fisted posturing of arms, crossed extension of legs and a high-pitched cry. These signs may be accompanied by seizures, backward arching of the neck (retrocollis) and trunk (opisthotonos), along with increased body temperature.

## Stage 3

It typically begins after the first week, with hypertonia, marked retrocollis, opisthotonos, stupor or coma. A scoring system can be used to assess the severity of the condition (**Table 3**).

After several months, in patients who survive, chronic bilirubin encephalopathy (kernicterus) develops. Classical kernicterus is a well-described clinical tetrad of abnormal movements and muscle tone, auditory processing disturbance with or without hearing loss, oculomotor impairments, especially that of upward vertical gaze, and dysplasia of the enamel of deciduous teeth.

Subtle kernicterus or bilirubin-induced neurologic dysfunction (BIND) refers to individuals with subtle neurodevelopmental disabilities without classical findings of kernicterus (**Table 4**).

## Prevention of Bilirubin Neurotoxicity

Factors that increase susceptibility to neurotoxicity in the jaundiced neonate are mentioned in **Box 2**. Numerous recent epidemiological studies have shown increasing trends in the prevalence of kernicterus. A plausible reason for this is the failure to practice accepted guidelines for the management of neonatal jaundice amongst pediatricians. Under-estimating severity of jaundice visually and lack of concern regarding the neurotoxic potential of bilirubin are also contributory factors. Compared with Western data, kernicterus has been reported at lower levels of peak TSB in India. Proposed mechanisms included late referrals, concomitant morbidities, higher incidence of G6PD deficiency and genetic increase in blood-brain barrier permeability. In a study at a tertiary care center in northern India, 21.8% neonates with non-hemolytic jaundice and TSB greater than and equal to 18 mg% had features of kernicterus when brought to the hospital. In another study, about 10% of neonates with TSB of 20–25 mg/dL presented with established neurological deficits. In a study on term infants with hyperbilirubinemia of mixed etiology, 10 out of 15 neonates with TSB of 21–25 mg/dL developed transient abnormalities in BAER and 11% had developmental delay at 1 year of age. These studies suggest that more importance needs to be given to babies with jaundice. Protocols regarding early discharge, appropriate follow-up, evaluation of TSB level based on the infant's age in hours and recognition of risk factors for severe hyperbilirubinemia are available and need to be followed meticulously to prevent unacceptable neurological sequelae.

## ASSESSMENT OF THE JAUNDICED NEONATE

Modified Maisels criterion is a useful initial clinical tool to decide if jaundice is pathological and includes any of the following:

- Clinical jaundice within the first 24 hours of life
- TSB levels increasing by more than 0.2 mg/dL (3.4  $\mu$ mol/L) per hour or 5 mg/dL (85  $\mu$ mol/L) per day
- Total serum bilirubin concentration exceeding the 95th percentile for age (in hours)
- Direct bilirubin concentration exceeding 1.5–2 mg/dL (26–34  $\mu$ mol/L)
- Clinical jaundice persisting for more than 2 weeks in a full-term infant.

The maternal and birth history, condition of neonate and physical findings all give clues as to the likely etiology of the

**Table 3** Bilirubin-induced neurologic dysfunction (BIND) score rating for awake or sleep states in infants (> 34 weeks' gestational age) with hyperbilirubinemia

Signs	Sleep state	Mild	Moderate	Advanced
Score rate		1	2	3
Mental	Awake	Agitated	Irritable	Seizures
	Sleep	Poor arousal	Lethargic	Semicoma
Tone	Awake	Hypertonia	Arching	Opisthotonos
	Sleep	Hypotonia	Limp	Flaccid
Cry	Awake	Shrill	Piercing	Inconsolable
	Sleep	Weak	Whimper	Almost absent
BIND score (1–9)		1–3	4–6	7–9
Automated auditory brainstem response (AABR) that is referred as an additional score. Thus, infant with a score of 3 plus a referred AABR = total BIND score of 4.				

Abbreviation: BIND, bilirubin-induced neurologic dysfunction.

Source: Johnson L, Bhutani VK. The clinical syndrome of bilirubin-induced neurologic dysfunction. *Semin Perinatol.* 2011;35:101-13.

**Table 4** Classification of bilirubin neurotoxicity (kernicterus)

Subtype	Description
Classic kernicterus	Classic triad or tetrad of: <ol style="list-style-type: none"> <li>1. Auditory neuropathy/auditory dyssynchrony <math>\pm</math> hearing loss or deafness</li> <li>2. Neuromotor symptoms, e.g., dystonia, hypertonia <math>\pm</math> athetosis</li> <li>3. Oculomotor paresis of upward gaze</li> <li>4. Enamel dysplasia of the deciduous teeth</li> </ol> Note that the oculomotor and dental criteria may be variably present or absent
Auditory kernicterus	Predominantly auditory symptoms, i.e., auditory neuropathy/auditory dyssynchrony with minimal motor symptoms
Motor kernicterus	Predominantly motor symptoms, e.g., dystonia $\pm$ athetosis with minimal auditory symptoms
Subtle kernicterus or bilirubin-induced neurological dysfunction (BIND)	Subtle neurodevelopmental disabilities without classical findings of kernicterus that, after careful evaluation and consideration, appear to be due to bilirubin neurotoxicity. These may include disturbances of sensory and sensorimotor integration, central auditory processing, coordination and muscle tone

Source: Shapiro SM. Definition of the clinical spectrum of kernicterus and bilirubin-induced neurologic dysfunction (BIND). *J Perinatol.* 2005;25:54-9.

## BOX 2 Factors that increase susceptibility to bilirubin neurotoxicity

- Birth asphyxia
- Caloric deprivation
- Temperature instability
- Prolonged hyperbilirubinemia
- Sepsis
- Lower gestational age
- Hypoalbuminemia
- Low birth weight
- Acidosis
- Hypercarbia
- Excessive hemolysis

jaundice (**Table 5**). Holistic clinical assessment of a jaundiced neonate includes assessment of etiology, risk factors for significant hyperbilirubinemia and clinical features of BIND. Clinical assessment based on cephalocaudal progression of jaundice as described by Kramer is still used though it is not accurate in dark-skinned babies and when the jaundice is decreasing (**Table 6**). Knudsen postulated that the cephalocaudal progression of jaundice can be explained by the conformational changes of the bilirubin-albumin complex. Although the initial binding of bilirubin to albumin is extremely rapid, final conformational

changes may not occur for about 8 min. Thus, blood leaving the reticuloendothelial system and going to the proximal parts of the body contains bilirubin that is less tightly bound to albumin than that which subsequently reaches the distal parts of the body. Bilirubin that is less tightly bound to albumin is more likely to precipitate as bilirubin acid in the phospholipid membranes in the skin and subcutaneous tissues, which is why the face appears jaundiced before the abdomen or the legs.

The World Health Organization (WHO), in its guidelines on neonatal jaundice, relies on clinical assessment for deciding

**Table 5** History and clinical examination in neonatal jaundice

Information	Significance
<i>Family history</i>	
Parent or family history of anemia	Hereditary hemolytic anemia like hereditary spherocytosis, G6PD deficiency
Previous sibling with neonatal jaundice	As above with possible genetic factors like TATA box mutations, isoimmune hemolysis or breastmilk jaundice
History of liver disease in family	Disorders such as cystic fibrosis, galactosemia, tyrosinemia, Crigler-Najjar syndrome
<i>Maternal history</i>	
Unexplained illness during pregnancy	Consider intrauterine infections particularly of TORCH group
Diabetes mellitus	Increased incidence of jaundice in IDMs
Drug ingestion during pregnancy	Ingestion of sulfonamides, nitrofurantoin, antimalarials may initiate hemolysis in G6PD deficient neonate
<i>History of labor and delivery</i>	
Vacuum extraction	Increased incidence of cephalhematoma or subgaleal hemorrhage
Use of oxytocin, epidural analgesia, excessive IV fluids	Increased incidence of hyperbilirubinemia due change in blood osmolarity
Delayed cord clamping	Increased incidence of polycythemia
Low Apgar score/resuscitation	Increased incidence of jaundice in asphyxiated infants
<i>History</i>	
Delayed passage of meconium	Increased enterohepatic circulation
Dark-colored urine, staining diapers with or without pale colored stools	Consider cholestasis after ruling out dehydration. Needs urgent evaluation
Breastfeeding failure	Results in delay in bilirubin conjugation and increased enterohepatic circulation
Vomiting	Suspect sepsis, galactosemia, or pyloric stenosis
<i>Physical examination</i>	
Preterm/late preterm infant	At-risk for significant hyperbilirubinemia due to immaturity of bilirubin metabolism
Sick newborn: on inotropes, ventilation, etc.	Lower threshold of TSB for specific treatment due to increased risk of bilirubin toxicity
Temperature instability	Lower threshold of TSB for specific treatment due to increased risk of bilirubin toxicity, consider sepsis
Excessive weight loss	Breastfeeding failure jaundice needs to be considered
Excessive lethargy, tone abnormalities	Early features of BIND, sepsis
Small for gestational age	Infants frequently polycythemic
Head size	Microcephaly: seen with intrauterine infections
Cephalhematoma	Significant breakdown of bilirubin with prolonged jaundice
Plethora	Polycythemia
Pallor	Suspect hemolysis
Petechiae	Suspect congenital infection, overwhelming sepsis
Appearance of umbilical stump	Omphalitis and sepsis may produce jaundice
Hepatosplenomegaly	Suspect hemolytic anemia or congenital infection
Optic fundus abnormalities	Chorioretinitis suggests congenital infection
Umbilical hernia	Consider hypothyroidism

*Abbreviations:* G6PD, glucose-6-phosphate dehydrogenase; TSB, total serum bilirubin; IDM, insulin-dependent diabetic mothers; TORCH, toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex; BIND, bilirubin-induced neurologic dysfunction.

**Table 6** Dermal staining and level of serum bilirubin

Area of body	Range of TSB (mg/100 mL)
Face	4–8
Upper trunk	5–12
Lower trunk and thighs	8–16
Arms and lower legs	17–20
Palms and soles	> 20

need for PT or referral. Jaundice is labeled severe if it appears on day 1 or involves arms and legs on day 2. Jaundice on palms and soles are considered a danger sign, requiring admission. These criteria are useful in settings where in-house facilities for TSB are not available, during home visits by peripheral health workers or in a district hospital/first referral unit during off-working hours. However, reliability of clinical assessment of bilirubin by different cadres of health workers is debatable and needs to be studied.

In the clinical assessment of a case of hyperbilirubinemia one should ask the following questions:

- *Is it physiological or pathological?* Appearance of jaundice within 24 hours, increase in serum bilirubin beyond 5 mg/dL/day, peak levels above the expected normal range, presence of clinical jaundice beyond 2 weeks and conjugated bilirubin (dark urine staining the clothes) would be categorized under pathological jaundice.
- *Is it hemolytic?* Onset of jaundice within 24 hours, presence of pallor or hepatosplenomegaly or suggestive family history of significant early-onset jaundice should raise a suspicion of hemolysis.
- *Is there a serious underlying condition?* Lethargy, poor feeding, failure to thrive, hepatosplenomegaly, temperature instability or apnea may be a marker of an underlying serious disease which could be either sepsis, urinary tract infection, a serious metabolic problem or bilirubin encephalopathy.
- *Is there cholestasis?* Presence of jaundice beyond 2 weeks, dark urine (staining the diaper) or pale colored stools would suggest cholestatic jaundice.

### Laboratory Assessment

Measurement of TSB can be done by simple colorimetric method, the prototype of which is the van den Bergh test which is a modification of the Ehrlich diazo reaction. Conjugated bilirubin gives a direct test while unconjugated bilirubin is indirectly calculated. Amongst the automated methods, newer versions such as Ektachem system are more accurate than others as it gives accurate estimates of  $\delta$ -bilirubin as well. High performance liquid chromatography, which gives the most accurate value of different fractions of bilirubin, is costly and not easily available. Spectrophotometry measures absorbance of bilirubin near 460 nm light spectrum. Inference by hemoglobin is resolved by analysis of a two-component system.

*Transcutaneous bilirubinometry* is a noninvasive technique of assessment of bilirubin, which is a useful screening tool. Second generation, hand-held bilirubinometers display TSB in mg/dL and  $\mu\text{mol/L}$  on a liquid-crystal display (LCD) screen. The calibration-tip fitted equipment is placed on the forehead of the baby and switched on. The equipment usually averages five readings. Use of a small PT patch, which can be removed and replaced, is in vogue for keeping a measurement area unexposed to light in babies under PT. This helps in giving more accurate readings. The recurrent expenditure is in the requirement of a new calibration tip for each reading. The advantage is that it a noninvasive point-of-care estimation. However, accuracy depends on the quality of

the equipment. Other investigations that need to be carried out in a jaundiced baby depend on the clinical presentation and clinical course and are given in **Table 7**.

### MANAGEMENT

A number of guidelines are available from different countries which lay down approaches to stratify, detect, treat and follow-up at-risk babies for significant hyperbilirubinemia so as to prevent the development of its neurotoxic sequelae. The most commonly used nomogram is that of American Academy of Pediatrics (AAP). The National Neonatology Forum (NNF) has adapted many of these in its own guidelines (**Box 3**).

### Predischarge Risk Stratification

Predischarge risk stratification needs to be done so as to devise an effective protocol for the follow-up of babies with neonatal jaundice. The AAP guidelines have identified certain risk factors which, when combined with hour-specific TSB based on nomograms, can be used to identify high-risk babies who can be followed up more closely. This predischarge risk stratification may need to be

**Table 7** Laboratory evaluation of the jaundiced neonate

Problem	Assessments
Jaundice in first 24 hours	TSB, Hb, PCV, peripheral smear for hemolysis, reticulocyte count, direct Coombs, G6PD screen
Jaundice in a sick neonate	TSB, sepsis screen, blood cultures, LFT, TORCH titers
Jaundice present at or beyond age 2 weeks, or sick infant	Total and direct (conjugated) bilirubin level If direct bilirubin elevated, evaluate for causes of cholestasis Thyroid and galactosemia screen

*Abbreviations:* TSB, total serum bilirubin; Hb, hemoglobin; PCV, packed cell volume; G6PD, glucose-6-phosphate dehydrogenase; LFT, liver function test; TORCH, toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex.

modified in the Indian setting due to a higher prevalence of G6PD deficiency, lower albumin at birth and seasonal variations. Besides, it is not always possible in our setting to estimate a predischarge TSB/transcutaneous bilirubin. However, it is still prudent to stratify babies based on known risk factors especially in cases of early hospital discharges. The NNF of India has brought out guidelines for follow-up of babies with jaundice after discharge (**Table 8**).

### Phototherapy

The primary aim of PT is to convert unconjugated, lipid-soluble bilirubin into a nondangerous form so as to prevent it from entering the brain and causing neuronal damage. Bilirubin is a pigment that absorbs light best at a wavelength of 450 nm. When light in this spectrum is delivered to the skin, the bilirubin rapidly forms configurational isomers from its native form, 4Z, 15Z. The most abundant of these isomers is 4Z, 15E and accounts for 20% of TSB in babies receiving PT. However, these isomers are reversible as soon as the lights are switched off and are not the main means of sustained reductions of TSB. The formation of structural isomers, of which the most prominent is lumirubin, is an irreversible process and is the main basis of reduction of TSB. The formation of lumirubin is directly proportional to the intensity of the PT. Photo-oxidation products are also formed but do not play an important role in the elimination of bilirubin. Rebound increase in serum bilirubin can occur after stopping PT after an apparent initial reduction of TSB.

**Table 8** NNF India guidelines for follow-up of babies for hyperbilirubinemia after discharge from hospital

Scenario	Age at discharge	Follow-up
No risk factors present*	24–72 hours	48 hours after discharge
	> 72 hours	Follow-up optional
Risk factors present**	24–48 hours	24 hours after discharge**
	49–72 hours	48 hours after discharge**
	73–120 hours	48 hours after discharge

\*The risk factors for consideration would include history of jaundice needing treatment in previous sibling, setting of blood group incompatibility, visible jaundice at discharge, gestation less than 38 completed weeks, high prevalence of G6PD deficiency, primipara mother, weight loss at discharge > 3% per day or > 7% cumulative weight loss.

\*\*May need a repeat visit depending on physician's assessment.

### Phototherapy Devices

The efficacy of PT is influenced by the following factors: (1) the spectrum of light delivered, blue-green region being the most effective; (2) the energy output or irradiance of the PT light, measured in  $\mu\text{W}/\text{cm}^2/\text{nm}$ ; and (3) the surface area of the infant exposed to PT (the spectral power is the product of the irradiance and the surface area exposed); (4) initial bilirubin values. Brief details of different devices available and technique of administration, impact, monitoring and side effects are given in **Box 4**. Clinical trials have shown that none of the devices are superior to one another. However, the LED lights have a longer life (> 20,000 hours), lower heat output, and lower infrared emission besides being of reasonable cost and hence are preferred. Intensive

PT needs to be administered in babies nearing bilirubin thresholds for ET and double surface PT is the preferred modality whenever feasible. To be labeled as intensive, PT should be continuous, with as much spectral power as possible.

### Initiation of Phototherapy

For babies born more than 35 weeks gestation, AAP guidelines recommended for initiation of PT are based on risk factors (prematurity, sickness) along with TSB levels. Babies more than 38 weeks who are well may be started on PT at TSB levels of 12 mg% at 24 hours and 16 mg% at 48 hours and 18 mg% at 72 hours. For high-risk babies (< 35 weeks or sick) the threshold for starting PT should be 2/3rds of these values. These recommendations may need to be modified for Indian setting. Since AAP guidelines specify therapy only till 7 days postnatal age and evidence is lacking for starting thresholds beyond this age, bilirubin thresholds for babies presenting beyond this duration should be considered as at day 7.

For babies less than and equal to 35 weeks period of gestation, it is generally recommended to treat hyperbilirubinemia at lower levels in comparison to term infants. The general guide is to start PT when TSB is 0.5% and 0.75% of the body weight in healthy and sick infants respectively and do ET when TSB is more than 1% of

**BOX 4 Facets of phototherapy****Classification of light source**

1. Fluorescent-tube devices
2. Metal halide bulbs
3. Light-emitting diodes (LEDs)
4. Fiber-optic cables

**Standards for phototherapy devices**

**Light wavelength:** 460–490 nm most effective. Special blue (BB) compact fluorescent lamps (CFL) and high-intensity Gallium nitrite LEDs also effective and long-lasting.

**Measuring light irradiance:** Different types of fluxmeters/dosimeters exist. It is best to use that given by the manufacturer. AAP recommendation: At least  $30 \mu\text{W}/\text{cm}^2/\text{nm}$ . Doses  $>65 \mu\text{W}/\text{cm}^2/\text{nm}$  may have unknown side effect. Useful life of bulbs not to exceeded. Footprints for measures to be taken from several sites of body.

**Optimal body surface area (BSA):** Should be > 90%, change of position every 2–3 hours to maximize BSA exposed. Exposed BSA more important than number of phototherapy devices used. Minimize diapers, eye patch areas. Circumferential phototherapy important. If in incubator, phototherapy should be perpendicular to avoid reflectance.

**Impact of phototherapy:** Should be evident after 4–6 hours with fall in TSB of at least 2 mg/dL. Intensive phototherapy for very high TSB to avoid exchange transfusion.

**Monitoring**

Ensure adequate hydration, nutrition, and temperature control. Clinical improvement or progression of jaundice should also be assessed, including signs suggestive of early bilirubin encephalopathy such as changes in sleeping pattern, deteriorating feeding, pattern, or inability to be consoled while crying.

**Other issues**

**Use of eye patches:** No evidence to support. May increase conjunctivitis.

**Use of diapers:** To be used for hygiene, not necessarily for gonadal protection.

**Contraindication:** Congenital porphyria or those treated with photosensitizing drugs.

**Side effects**

Increased oxidant stress, lipid peroxidation, riboflavin deficiency. Recent clinical reports of other adverse outcomes (e.g., malignant melanoma, DNA damage, and skin changes) have yet to be validated. Phototherapy does not exacerbate hemolysis. Bronze baby syndrome occurs if phototherapy is administered in conjugated hyperbilirubinemia.

the bodyweight in grams. For babies born with birth weight less than 2,500 g, various thresholds that have been mentioned for PT and ET are given in **Box 4**.

### Stopping Phototherapy

Phototherapy may be discontinued when serum bilirubin level have fallen at least 2 mg/dL below the PT threshold for that postnatal age. If the underlying disease is hemolytic in nature or if PT has been initiated early and discontinued before the infant is 3–4 days old, a follow-up bilirubin measurement within 24 hours after discharge is recommended. For infants who are readmitted with hyperbilirubinemia and then discharged, significant rebound is rare, but a repeat TSB measurement or follow-up 24 hours after discharge is an option. However, clinically significant rebound increase in TSB after stopping PT have been found in cases of prematurity, direct Coombs test positivity and in those treated for less than 72 hours. These risk factors should be taken into account when planning post-PT follow-up.

### Exchange Transfusion

Removal of the neonate's blood in aliquots with replacement with safe blood has always been an option to remove bilirubin from the body rapidly. However, with better PT this modality is now being used rarely. Knowledge of this practice is important as it can be life and brainsaving.

### Indications

As per the NNF India guidelines, the decision to perform an ET is based on the TSB value for that postnatal age, level of sickness of the baby, the likely etiology and presence or absence of bilirubin encephalopathy. Important risk factors to consider exchange at lower TSB levels include presence of acidosis, low albumin level, blood-brain barrier disruption (e.g., intracranial hemorrhage, asphyxia, sepsis, meningitis), Coombs positive jaundice, G6PD deficiency, displacers of bilirubin (e.g., free fatty acids from intralipid, ibuprofen, ceftriaxone) and encephalopathy. One should consider an early ET in case of hydrops, history of previous sibling requiring exchange because of Rh isoimmunization, cord Hb < 11 g/dL, cord TSB > 5 mg/dL, rate of rise of TSB > 1 mg/dL/hour despite PT, any TSB > 12 mg/dL in first 24 hours and TSB > 20 mg/dL in the early neonatal period particularly if due to hemolysis (**Table 9**).

### Procedure

For Rh isoimmunization, the best choice would be O-negative packed cells suspended in AB-positive plasma. O-negative whole blood crossmatched with baby's blood group may also be used. For ABO isoimmunization, O group (Rh compatible) packed cells suspended in AB plasma or O group whole blood (Rh compatible with baby) should be used. In other situations, baby's blood group should be used. All blood must be crossmatched against maternal plasma as well (**Table 10**).

The blood volume required for ET is  $2 \times (80\text{--}100 \text{ mL/kg}) \times \text{birth weight in kg}$ . Though evidence suggests that the use of peripheral arterial route for exchange is associated with fewer complications than using the umbilical route, the procedure requires more expertise. The most common route used is the single umbilical catheter via the umbilical vein, which is inserted approximately 3 cm and 5 cm (in preterm and term babies respectively) with the use of appropriately matched blood, done in aliquots of 5–8% of bodyweight (**Fig. 1**). The procedure needs to be done under strict asepsis and hemodynamic monitoring. Though some studies have shown benefits of transfusing 20% albumin prior to ET, its routine use is not recommended.

**Table 9** Indications for phototherapy and blood exchange transfusion in low birth weight babies

Birth weight (grams)	Guidelines for phototherapy (mg/dL)		Consider exchange transfusion (mg/dL)
	Healthy infant	Sick infant	
< 1000	5–7	4–6	10–12
1,000–1,500	7–10	6–8	12–15
1,501–2,000	10–12	8–10	15–18
2,001–2,500	12–15	10–12	18–20

**Table 10** Choice of blood group for exchange transfusion

Maternal blood group	Infant blood group	Donor blood group
O	O or A or B or AB	O
A or B or AB	O or A or B or AB	Baby blood group or O group
Rh-negative	Rh-positive or negative	Rh-negative

**Figure 1** Exchange transfusion using umbilical venous route

### Emergency Approach to Neonatal Hyperbilirubinemia

A neonate presenting with severe hyperbilirubinemia should be urgently evaluated for features of acute bilirubin encephalopathy and must be initiated on intensive PT as an emergency measure even before all investigations are available. Since studies have shown that many such babies come from community with significant dehydration, IV fluids need to be administered. Besides, arrangements for ET must be made and undertaken if the dangerous bilirubin thresholds are reached.

### Additional Therapies

#### Intravenous Immunoglobulin

Intravenous immunoglobulin therapy inhibits hemolytic breakdown of RBCs by causing nonspecific blockade of Fc receptors in the reticuloendothelial system and has been used effectively in immune hemolytic anemia. In a meta-analysis which included seven studies that investigated the role of IVIG in hemolytic anemia, significant reduction in maximum TSB and the need

for ET has been reported. However, there was a trend toward increased need for packed cell transfusion due to anemia after first week of life. No significant difference was observed in a small randomized controlled trial comparing 0.5 and 1 g/kg dose of IVIG.

### Phenobarbitone

Phenobarbitone is a potent inducer of uridine diphosphate glucuronosyltransferase (UDPGT) and has, in addition, multiple actions at other levels of bilirubin metabolism in the liver. PB has been used in the prevention of neonatal jaundice for very low birth weight (VLBW) babies and in the treatment of hyperbilirubinemia of Crigler-Najjar syndrome, Dubin-Johnson syndrome and neonatal cholestasis. A meta-analysis of three studies has concluded that PB reduces peak serum bilirubin, duration and need of PT and need of ET in preterm VLBW neonates. In a recent study, on the role of prophylactic oral phenobarbitone in Rh-

HDN no significant reduction of total duration of PT or significant rebounds of TSB was found in the PB group.

### Fluid Supplementation

Studies have shown that provision of extra fluid to babies undergoing PT reduces the total duration of PT and also the need for ET significantly. Standard care consisted of conventional PT combined with 20 mL/kg per day of extra oral feeds (expressed breastmilk or formula) until PT is discontinued. However, routine IV fluid prescription to babies under PT is not recommended in view of the potential risk of sepsis and needs to be considered on case to case basis.

### Other Available Modalities

A list of various other pharmacological agents that have been tried in neonatal jaundice with its evidence and current recommendations is described in **Table 11**.

**Table 11** Pharmacotherapy for neonatal unconjugated hyperbilirubinemia

Drug	Mechanism of action	Evidence	Remark
Metalloporphyrin	Reducing bilirubin production by inhibiting heme oxygenase	Cochrane Three studies (N = 170); poor quality nonblinded trials Short-term benefits: lower maximum plasma bilirubin level, decreased need for phototherapy, fewer plasma bilirubin measurements and a shorter duration of hospitalization Photosensitivity rash—adverse effect	Routine use cannot be recommended Newer more safe molecules than Tin(Sn) metalloporphyrins evolving
Clofibrate	Increased elimination Reducing enterohepatic circulation	Cochrane Fifteen studies, 13 done in Iran, 2 in preterm, 13 in term. For preterm neonates, there was a significantly lower bilirubin level in the 100 mg/kg clofibrate after 48 hours  For the term neonates, there were significantly lower bilirubin levels in the clofibrate group after both 24 and 48 hours of treatment Significantly lower duration of phototherapy for both preterm and term neonates None of the studies reported on bilirubin encephalopathy rates, neonatal mortality rates, or the levels of parental or staff satisfactions with the interventions Loose stools, bloating may be side effect	Thirteen of the 15 studies done in Iran. Short-term benefits in term babies, Nonhemolytic setting  Long-term benefits not yet proven Single dose of clofibrate seems promising Larger studies required from different countries
Activated charcoal	Increased elimination  Reducing enterohepatic circulation	No recent evidence, seems to have nearly gone off practice with effective PT Quasi controlled study have shown activated charcoal beneficial as adjunct to PT. The combination drops TSB more than PT	Based on small studies  Activated charcoal and agar might be useful adjuncts to PT
Agar		Oral agar versus combination of agar + PT—Max drop in TSB with combination. Oral agar equally effective as PT	No recent large studies
Yinzhihuang	Chinese herb	Oral solution is a herbal extract with the main components of <i>Herba Artemisiae Scopariae</i> , <i>Scutellaria</i> , <i>Lonicera Japonica</i> and <i>Gardenia jasminoides</i>	For interest sake Apparently useful Not sure whether we have an Indian counterpart
Prebiotics		Prebiotics added to formula feeding results in more stools and lower TcB levels in healthy infants with moderate hyperbilirubinemia	An emerging option, in its early stages Not recommended at this point
D-Penicillamine	Probably influences Bil- Alb binding	Few studies early mid 70 seemed to reduce TSB levels; toxicity high	Historical with other safer treatments in line

Abbreviations: TSB, total serum bilirubin; PT, phototherapy; TcB, transcutaneous bilirubin.

## NEONATAL CHOLESTASIS

(Also See Section 37)

Neonatal cholestasis is defined as conjugated hyperbilirubinemia occurring in the newborn as a consequence of diminished bile flow. Conjugated hyperbilirubinemia in a neonate is defined as a serum direct/conjugated bilirubin concentration (*a*) greater than 1 mg/dL if the TSB is < 5 mg/dL; or (*b*) > 20% of TSB if the TSB is > 5 mg/dL. Conjugated hyperbilirubinemia is always pathological at any age and needs urgent evaluation. The issue here is not neurotoxicity (as the conjugated bilirubin cannot cross the blood-brain barrier) but hepatotoxicity as the pent-up bilirubin or the underlying etiology damages liver cells leading to chronic liver failure. The urgency in evaluation is mainly to rule in extrahepatic biliary atresia, a condition which requires time-bound surgical management. The outcomes of surgical interventions are better if performed before 2 months of age. A list of common causes of cholestasis is mentioned in **Box 5**. Special investigations include imaging like ultrasound of liver and gallbladder, radioisotope scan with hepatobiliary iminodiacetic acid scan and magnetic resonance cholangiography. It is usually not easy to make a definite diagnosis of the etiology in the early stages of the disease and when in doubt, a peroperative cholangiography is performed before surgery. In many cases of neonatal cholestasis, liver transplant is the only treatment option available.

### Follow-up

All neonates with significant hyperbilirubinemia must be followed up for hearing assessment and developmental delay.

### IN A NUTSHELL

1. Neonatal hyperbilirubinemia is a common condition in newborns.
2. Some known and many unknown risk factors predispose neonates to the risk of bilirubin neurotoxicity. This can vary from subtle manifestations such as BIND to the most severe form, namely kernicterus.
3. By following standard protocols, taking a detailed history, doing a thorough clinical examination, using available investigations judiciously and management modalities effectively and ensuring an adequate follow-up, prevention of these complications is possible.
4. Phototherapy still forms the backbone of effective management of unconjugated hyperbilirubinemia.
5. Neonatal cholestasis should be suspected clinically and investigated rapidly to rule out surgically treatable conditions.

## Chapter 14.4

# Infant of Diabetic Mother

*Srinivas Murki, Tejo Oleti Pratap*

Adult onset diabetes mellitus is an increasing problem due to the changing lifestyle and altered genetic factors. Recent evidence from India and other regions of the world report the incidence of diabetes complicating pregnancy ranging from 5% to 10%. Diabetes in a pregnant mother increases the risk of complications to the mother-fetal/infant dyad. When the onset of diabetes occurs prior to pregnancy, it is considered pregestational (type 1 or 2 diabetes mellitus diagnosed prior to pregnancy) and that which occurs during pregnancy is labeled as gestational diabetes. Although the incidence of gestational diabetes is more than the pregestational diabetes, there is an increasing trend in the incidence of the latter. A newborn born to a mother with pregestational diabetes has more complications than that born to a mother with gestational diabetes. Also the perinatal morbidity and mortality is higher in infants of poorly controlled diabetic mothers than those born to well-controlled diabetic mothers.

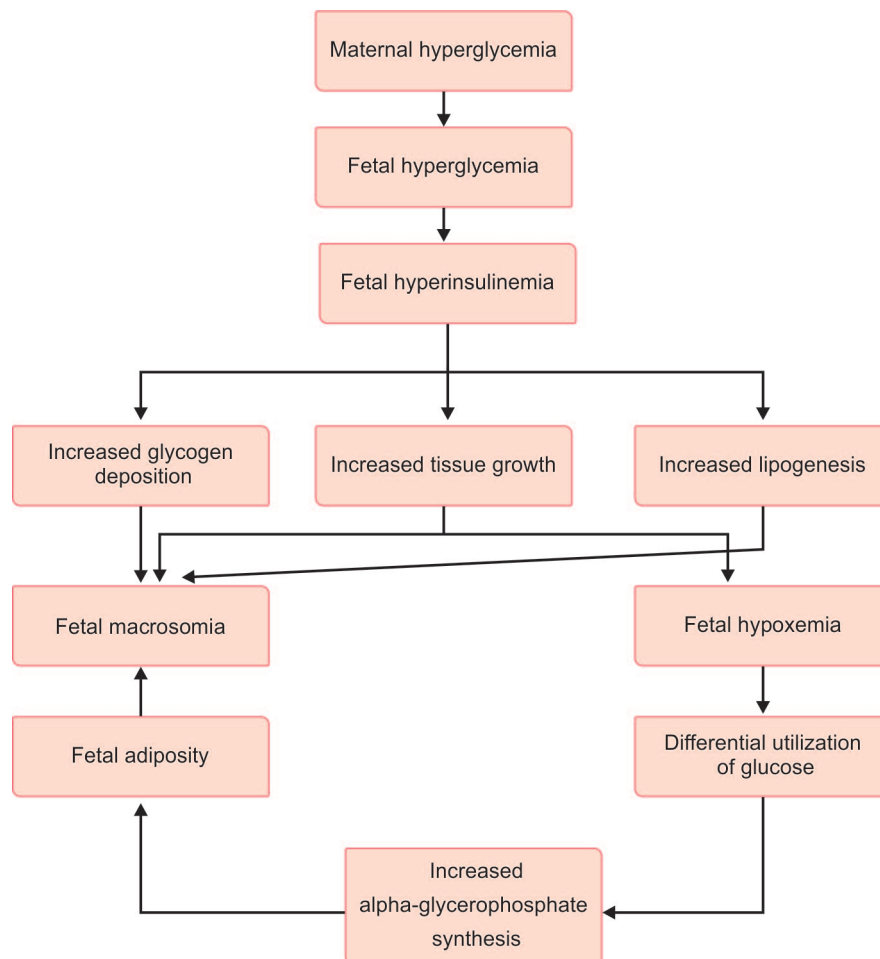

### PATHOGENESIS

Pederson in 1954 had postulated that uncontrolled maternal hyperglycemia has multiple effects on the developing fetus. Later in

Macfarlane CM et al. (1988) proposed a modified hypothesis to that of Pederson to explain pathways to fetal macrosomia in mothers with hyperglycemia (**Flow chart 1**). But, not all fetal complications are a direct consequence of maternal glycemic control. Prior to 20 weeks of gestation, fetal pancreatic islet cells usually do not secrete insulin in response to maternal hyperglycemia, and the effects at this period of gestation are the direct consequence of hyperglycemia. The fetal complications in later gestation are the result of fetal hyperglycemia, hyperinsulinemia or combined effect of both.

Poor control during the first trimester results in abortions or major malformations. When glycemic control is poor in the second trimester it is associated with higher risk of pregnancy-induced hypertension and preterm labor. Inadequate glycemic control in the third trimester is associated with fetal macrosomia and its attendant complications during delivery such as cesarean birth and birth trauma. It is also associated with higher neonatal complications associated with macrosomia such as respiratory distress syndrome, hypoglycemia and polycythemia. Fetal hyperglycemia with resultant fetal hyperinsulinemia contributes to increased fetal substrate uptake resulting in increased oxygen consumption making the developing fetus suffer from chronic hypoxemia. Fetal hypoxemia leads to altered utilization of glucose leading to metabolic acidosis in tissues and also increases the hypoxia in utero. Fetal hypoxia also results in increased amniotic fluid erythropoietin (EPO) levels. Increased red cell mass (polycythemia) due to high levels of erythropoietin leads to relative iron deficiency of major organs including brain and heart.

**Flow chart 1** Modified Pedersen hypothesis

## CLINICAL FEATURES AND NEONATAL COMPLICATIONS

Uncontrolled maternal glucose control during pregnancy is associated with a number of neonatal complications.

### Fetal Growth

Macrosomia or large for gestational age (LGA) is one of the cardinal features of infant of diabetic mother (IDM) especially when mothers have had poor glycemic control beyond 20 weeks of gestation. Large face with prominent cheeks, plethora, hairy pinna and excess body hair are the other common features seen in these neonates (**Fig. 1**). In the past the incidence of macrosomia amongst IDMs was reported to be about 60%, but with early diagnosis and more aggressive glycemic control, the reported incidence has dropped to less than 30%. Not all LGA infants born to diabetic mothers are macrosomic. In contrast to a constitutionally large infant where all anthropometric centiles (weight, length and head circumference) are proportionally higher, in IDMs, the weight centiles are disproportionately higher (usually above the 95th percentile) than the length and head circumference centiles. The expected difference between head circumference and chest circumference is often reduced (due to adiposity in the chest). A higher ponderal index, and *mid-arm circumference to head circumference ratio*, may guide in helping to differentiate an IDM LGA infant from other large for gestational age infants. Macrosomia in IDMs is a good predictor of the risk of metabolic problems such as hypoglycemia, hypocalcemia, and polycythemia. Large infants are more predisposed to shoulder dystocia and obstructed labor which increase the incidence of birth traumas (clavicular/humerus fracture, brs/phrenic nerve palsy, cephalhematoma/sub-galeal bleeds).

In contrast mothers with poorly controlled pregestational diabetes are at increased risk of having growth retarded or small for gestational age infants (probably due to associated diabetic vasculopathy).

### Malformations

Incidence of malformations is 3–8 times more common in IDMs than controls. Some of the common malformations associated with maternal diabetes include:

- **Central nervous system:** Neural tube defects, anencephaly and holoprosencephaly.
- **Cardiac:** Ventricular septal defect (VSD), patent ductus arteriosus, transposition of great vessels and truncus arteriosus.
- **Gastrointestinal tract:** Lazy left colon syndrome (also called small left colon syndrome), intestinal duplications and atresia.
- **Genitourinary:** Ureteral duplication, renal agenesis, hydronephrosis.
- **Caudal regression syndrome,** flexion contractures, vertebral defects and cleft palate.

Although cardiac malformations are more common, caudal regression syndrome is very specific to uncontrolled maternal diabetes.

### Hypoglycemia

Hypoglycemia is commonly seen in macrosomic or growth retarded infants born to diabetic mother compared to infants born appropriate for gestational age. In the large infants, hypoglycemia is usually a reactive phenomenon secondary to persistence of fetal hyperinsulinism into the neonatal period. Hypoglycemia may be compounded additionally by the perinatal anoxia, which increases catecholamine and glucocorticoid levels and contribute to glycogen depletion. The high neonatal insulin levels tend to persist for up to 72 hours and may rarely last up to one week. On the other hand, in the growth retarded infants, hypoglycemia is due to depletion of

**Figure 1** Infant of diabetic mother: Macrosomia, relative small head compared to body, chubby cheeks, plethoric face and hairy pinna

glycogen reserves. Symptoms of hypoglycemia include jitteriness, seizures, tachypnea, apnea and sweating. IDMs would need the close monitoring of blood glucose, and sufficient exogenous glucose to maintain glucose levels above 40 mg/dL.

### Hypocalcemia and Hypomagnesemia

Both hypocalcemia and hypomagnesemia (serum magnesium < 1.5 mg/dL) are probably due to delayed transition from fetal to neonatal parathyroid function. Both could be seen in up to 50% of IDMs. Hypomagnesemia may also be due to maternal magnesium deficiency resulting from increased magnesium loss in the urine among mothers with glycosuria. Symptoms of hypocalcemia and hypomagnesemia are similar, and include jitteriness, convulsions, sweating, and tachypnea. The symptoms usually appear in the first 24–72 hours.

### Respiratory Distress

Infants of diabetic mothers are more likely to develop respiratory distress after birth which may be due to respiratory distress syndrome (due to surfactant deficiency), transient tachypnea of newborn (due to cesarean delivery and/or birth asphyxia). IDMs are more likely to develop RDS compared to gestation matched infants born to nondiabetic mothers, as insulin antagonizes cortisol induced maturation of type II alveolar cells (and therefore decreased surfactant synthesis); this risk being seen up to 38 weeks of gestation age. Persistent pulmonary hypertension may complicate the course of RDS, particularly with co-existing polycythemia.

### Others

**Cardiac failure** Asymmetric septal hypertrophy or cardiomyopathy may be seen in up to 30% of IDMs, but only a third of them go on to develop frank congestive heart failure. Septal hypertrophy is the direct consequence of fetal hyperglycemia inducing hyperinsulinism and deposition of glycogen in the cardiac septum. Symptoms of cardiac failure can be exacerbated in the presence of polycythemia.

**Hyperbilirubinemia** IDMs are increased risk of hyperbilirubinemia because of higher red cell mass, ineffective erythropoiesis and delayed maturation of enzymatic pathways in liver.

**Polycythemia** Polycythemia defined as hemoglobin more than 20 g/dL or a hematocrit more than 65% is reported in up to 20–30%

**Table 1** Fetal and neonatal complications in neonates born to mother with diabetes mellitus and their management

<i>Problem</i>	<i>Pathophysiology</i>	<i>Prevention/management</i>
Malformations	Maternal hyperglycemia during the initial 14 weeks of gestation alters the maturation of different growth factor pathways and causes dys-organogenesis	Better periconceptional glycemic control Folic acid prophylaxis
Recurrent abortions	Uncontrolled maternal hyperglycemia and other associated morbidities lead to first trimester abortions	Better periconceptional glycemic control
Prematurity	Uncontrolled maternal hyperglycemia, fetal macrosomia, IUGR and iatrogenic termination	Good antenatal care and fetal monitoring Good glycemic control during pregnancy Antenatal steroids if expected delivery between 24 weeks and 34 weeks of gestation
Intrauterine death	Maternal microvasculopathy leads to increased placental resistance. Disproportionate fetal growth which is not met by the normal placenta predisposes them to adverse outcomes	Good antenatal care and fetal monitoring Good glycemic control during pregnancy
Macrosomia	Fetal hyperinsulinemia leads to increased adiposity and organomegaly. However, it will not affect the head size as brain glucose utilization is not dependent on fetal insulin levels	Better periconceptional glycemic control Good antenatal care and fetal monitoring Better antenatal glycemic control Care during delivery to avoid birth trauma
Growth retardation	Maternal microvascular changes leads to increased placental resistance and impairs the nutritional needs of the growing fetus	Better periconceptional glycemic control Good antenatal care and fetal monitoring Maternal nutrition and supplements
Respiratory distress syndrome	Fetal hyperinsulinemia impairs the maturation of surfactant. It will inhibit the incorporation of choline component in DPPC. It also impairs the release of various growth factors for production of mature surfactant and maturation of ion channels required for clearance of lung fluid	Better antenatal glycemic control Antenatal steroids as appropriate Provide adequate respiratory support—oxygen/CPAP/ventilation
Hypoglycemia (glucose < 40 mg/dL)	Fetal hyperinsulinemia, macrosomia, perinatal asphyxia and feeding difficulties predisposes these neonates to hypoglycemia	Screening blood sugars at 1, 6, 12, 24, 48 and 72 hours of life Supervised and schedule feeding, lactation support Early and aggressive therapy to prevent recurrence and seizures
Hypocalcemia (Total serum calcium level < 7 mg/dL)	Delayed transition from fetal to neonatal parathyroid control, Vitamin D antagonism due to elevated cortisol levels at intestinal level, asphyxia and relative prematurity at birth complicate the calcium metabolism	Monitor for jitteriness and other symptoms Screening for serum calcium at 2 and 12 hours Calcium supplementation for symptomatic newborns
Hypomagnesemia (< 1.5 mg/dL)	All the factors that operate in calcium metabolism will also operate for magnesium metabolism. Other factors include low maternal magnesium levels due to excess urinary losses secondary diabetic nephropathy	Monitor for symptoms of hypocalcemia Screen for low magnesium levels in nonresponsive hypocalcemia Treat symptomatic neonates with magnesium supplement
Hyperbilirubinemia	Excess red blood cell mass and relative immaturity of hepatic conjugating enzymatic pathways will increase the bilirubin levels	Monitor the neonates for hyperbilirubinemia Provide follow-up for early discharges
Feed intolerance	Prematurity, perinatal asphyxia and altered bowel motility in these neonates causes feed intolerance	Monitor for early symptoms Rule out other causes such as lactation counseling
Polycythemia	Intrauterine hypoxia leads to excess production of erythropoietin and other growth factors. This results in increased erythroid mass (around 30%)	Screening hematocrit at 2, 6, 12 and 24 hours of life Adequate fluids and liberal feeding Partial exchange transfusion (PET) in symptomatic cases
Hypertrophic cardiomyopathy	Fetal hyperglycemia with secondary hyperinsulinemia contributes to hypertrophy of ventricular wall and septum. Septal hypertrophy causes diastolic dysfunction	Screening by fetal/neonatal ECHO Management of heart failure B-blockers for improving the diastolic function Avoid digoxin and prolonged inotropic support

Abbreviations: IUGR, intrauterine growth restriction; CPAP, continuous positive airway pressure.

of IDMs at birth. Polycythemia can result in increased blood viscosity and if persistent can result in seizures, stroke, necrotizing enterocolitis and renal vein thrombosis. Polycythemia infants are usually plethoric, lethargic and may have jitteriness.

**Iron deficiency** Several studies have shown that two-thirds of IDMs and most of IDMs who are macrosomic are iron deficient at birth. Most of these infants have low serum ferritin levels; the more severely affected infants would also have increased total iron

binding capacity, decreased transferring saturations and increased free erythrocyte protoporphyrin levels. Perinatal iron deficiency may place IDMs at increased risk of neurologic injury when associated with perinatal anoxia.

**Central nervous system** IDMs are likely to have neurologic symptoms such as depression, irritability, jitteriness and convulsions. These could be due to multiple factors—perinatal anoxia, birth trauma, hypoglycemia, hypocalcemia, polycythemia, and hypoxia.

## MANAGEMENT

Common perinatal problems and their management are summarized in **Table 1**. Periconceptional glycemic control is required to avoid embryopathy and fetal wastage. Early screening, good glycemic control during pregnancy with diet, exercise and insulin would improve the perinatal outcomes.

**Delivery room management** There must be a team of well trained nurses and pediatricians along with the obstetrician to manage the birth of an IDM because of the risks of shoulder dystocia and perinatal asphyxia and depression. The team must be capable to effectively resuscitating these babies at birth. The team must also be able to perform a complete physical examination of the infant to identify malformations and stabilize the infant in case of respiratory distress.

**Monitoring in the NICU** The infant must be closely monitored for respiratory distress, hypoxia, hypoglycemia and polycythemia at frequent intervals (**Table 1**).

**Feeding and hypoglycemia** IDMs who are asymptomatic should be allowed to breastfeed which should be initiated within the first hour of birth. Infants with poor sucking may be fed by orogastric feeding. Monitoring for blood sugar should continue as per frequency outlined in **Table 1**. Those who develop hypoglycemia should be treated using standard guidelines (Chapter 14.4).

**Respiratory distress** All IDMs with respiratory distress must be provided oxygen supplementation and ventilation as required. All these infants should have a chest skiagram to differentiate RDS, transient tachypnea of the newborn (TTN), pneumonia or pneumothorax. If chest X-ray suggests RDS, these infants may need surfactant treatment in addition to respiratory support. TTN would only require oxygen or rarely ventilator support for about 24–72 hours. However, all infants must undergo an echocardiography to identify presence or absence of a cardiac malformation and asymmetrical septal hypertrophy.

**Asymmetrical septal hypertrophy** Symptomatic infants should be treated with beta-blockers as it improves outflow obstruction. Oral propranolol is started at 0.25 mg/kg/dose q6h, increase as needed to a maximum of 3.5 mg q6h. If using intravenous route starting dose is 0.01 mg/kg over 10 min q6h, increase as needed to maximum to 0.15 mg/kg q6h. Propranolol administration must be under careful blood pressure monitoring.

**Polycythemia** All symptomatic infants and those with a hematocrit more than 70% must undergo partial exchange transfusion to reduce viscosity.

**Hypocalcemia and hypomagnesemia** Only symptomatic infants should be treated. Hypocalcemia should be treated by infusing 2 mL/kg of 10% calcium gluconate (adequate equal dilution) through a large vessel (to prevent extravasations and subcutaneous necrosis) slowly under cardiac monitoring. This should be followed by 75 mg/kg/day of calcium as infusion. Refractory or recurrent

hypocalcemia associated with hypomagnesemia can be treated by 0.12 mL/kg of 50% magnesium sulphate intramuscularly (this would increase the serum magnesium by 1 mg/dL over 6 hours and correct the hypocalcemia).

## OUTCOMES

The prenatal exposure of the fetus to hyperglycemia and its postnatal consequence may result in adverse neurological and neurodevelopmental outcomes. Neurodevelopment outcome of IDM with good euglycemia during antenatal period is similar to that of normal controls. However, poorly controlled blood sugars in the antenatal period may result in adverse long-term outcomes. IDMs have a higher risk than their peers for diabetes mellitus, impaired glucose intolerance and obesity. The lifetime risk of infants of diabetic mother for type 1 diabetes mellitus is 2% compared to 0.3–0.4% in infants not having any family history.

### IN A NUTSHELL

1. Poor glycemic control in pregnancy is associated with increased risk of adverse fetal and neonatal outcomes.
2. Fetal macrosomia is associated with increased risk of perinatal asphyxia, birth trauma, neonatal hypoglycemia, polycythemia and asymmetrical septal hypertrophy.
3. All IDMs must be carefully examined for malformations and monitored for respiratory distress, hypoglycemia, hypocalcemia and polycythemia.
4. All IDMs with respiratory distress must undergo a chest skiagram and echocardiography (to exclude cardiac malformation and asymmetric septal hypertrophy).
5. Only symptomatic IDMs need to manage in NICU, the others can be managed in a well baby area with adequate monitoring.

## Chapter 14.5

# Neonatal Hypoglycemia

Shiv Sajjan Saini, Praveen Kumar

Diagnosis and management of neonatal hypoglycemia is both challenging and controversial. There is no clear definition and *safer limits* of blood sugar levels in neonates. These limits might conceptually be different among neonates of variable gestational ages with different maturity levels, influence of intrauterine growth retardation, and levels of illness severity. What makes it even more complex is the perinatal adaptation after birth. The fine balance between glucose utilization and production is responsible for maintenance of stable blood sugar levels. This balance is secondary to coordinated changes in the concentrations of insulin and the counter-regulatory hormones, principally growth hormone, cortisol, glucagon, and catecholamines. However, immaturity of these pathways leads to disturbances in glucose homeostasis mainly hypoglycemia. The neonatal hypoglycemia is usually transient but less frequently persistent. Hypoglycemia in neonatal period may be asymptomatic or can present with ominous signs like seizures. Any type of hypoglycemia, however, can lead to significant neurological morbidity and long-term complications. Hence, neonatal hypoglycemia should always be given urgent attention. In this chapter, the authors have reviewed the definition, pathophysiology, methods of measurement of blood sugar, prevention, and treatment of neonatal hypoglycemia.

## PHYSIOLOGICAL CONSIDERATIONS

The fetus is mainly dependent on transplacental transfer of nutrients including glucose. Although fetus is equipped with gluconeogenic enzymes at 2 months, endogenous glucose production is not physiological in fetal life. Glucose crosses the placenta by facilitated diffusion and hence fetal blood glucose concentrations are slightly lower than mother. A part of maternal glucose is converted by the placenta to lactate, which is released into the fetal and maternal circulation in 1:3 ratio. Although glucose is the principal energy substrate for the human fetus, lactate acts a major substrate for both oxidative and non-oxidative metabolism. At birth, glucose level in the umbilical venous blood is 80–90% of maternal levels. There is a sharp decline in neonatal blood glucose concentration after cord clamping due to sudden cessation of maternal glucose supply. The neonatal blood glucose concentration reaches its nadir by 1 hour of age before recovering and stabilizing by 3 hours of life.

This postnatal adaptation is achieved with the help of metabolic changes including hepatic glycogenolysis, gluconeogenesis; lipolysis, fatty acid  $\beta$ -oxidation with generation of ketone bodies, and proteolysis that generates lactate and other substrates for gluconeogenesis. There is substantial variability in blood glucose levels during postnatal adaptation, both within individual neonates and among neonates of different gestational ages and growth patterns. There are major endocrine changes including fall in plasma insulin levels, marked rise in plasma glucagon, catecholamine surge after stress of birth, and rise in growth hormone concentration. Ketone bodies and lactate serve as important alternative fuels for maintaining cerebral energy supply. Newborn brain has 5–40 fold greater capacity to utilize ketone bodies compared to that of infant or adult brain. Lactate appears to be important for neonates in the immediate postnatal life.

There is a greater fall in blood glucose levels among preterm neonates after birth as compared to term infants. There are conflicting reports of glucose production rates in preterm neonates

as compared to term neonates in postnatal life. Some reports suggest higher circulating levels of gluconeogenic substrates and low activity of microsomal glucose-6-phosphatase (the final enzyme of glycogenolysis and gluconeogenesis) leading to lower levels in preterm neonates; while some showed similar glucose production rates as compared to term neonates. However, preterm infants, in the first week of postnatal life, lack a mature counter-regulatory ketogenic response to low blood glucose levels which can persist during first 8 postnatal weeks and even beyond. Preterm neonates display higher plasma immunoreactive insulin concentrations at low blood glucose levels as compared to term counterparts. The basal insulin concentrations decrease with increasing maturity.

## DEFINITION

The *low level* of blood glucose is difficult to define in neonates because of several reasons. Neonates of various gestation ages have variable maturity of nervous system and variable capacity to manifest the signs and symptoms of hypoglycemia. The *critical limit* of blood glucose levels required for integrity of neonatal brain function is currently unknown. Additionally, hypoglycemia often occurs in association with other morbidities, which in turn could potentiate brain injury. Along with comorbidities, the *safe glucose limits* are likely to be higher as compared to isolated hypoglycemia. Various definitions of hypoglycemia have been proposed by different authors.

Conventionally, hypoglycemia is defined by a value lying outside the normal distribution obtained in healthy neonates, i.e., less than 2 standard deviations (SD). The statistical abnormality is not sine qua non with biological abnormality. Additionally, minus 2 SD cut-off values might vary with the gestational age, postnatal age, type of feeding and physiological state. Finally this cut-off does not consider the complexities of the metabolic milieu, the availability of alternative substrates and the clinical condition of the baby. The clinical manifestations of hypoglycemia (i.e., lethargy, tremor, sweating, cyanosis, jitteriness, hypotonia, coma, and seizures) are well recognized and may be useful to define hypoglycemia. However, majority of these signs are nonspecific and certain signs like jitteriness may be seen even in normal healthy neonates. More importantly, the clinical definition may not cover neonates with asymptomatic hypoglycemia, which can cause hypoglycemic brain injury. Furthermore, the levels of blood glucose at which clinical manifestations appear may be different from the levels at which biochemical injury occurs leading to long-term neurological sequelae. Hence, clinical definition alone cannot be used for clinical purposes, nevertheless presence of clinical signs of encephalopathy such as decreased level of consciousness or seizures should put physician on red alert. Stimulation of counter-regulatory hormonal response at *threshold* blood glucose concentrations can also be used to define hypoglycemia. However, there is little information available on this complex issue. Additionally, preterm neonates have limitations in mounting a mature counter-regulatory response to low blood glucose levels, making this judgment unsuitable for them. Change in neurophysiological functions, e.g., evoked potentials in response of *low glucose* levels, could be another way to define hypoglycemia. The cut-off levels associated with adverse neurodevelopmental outcomes could also be used to define hypoglycemia. However, there is limited literature about these definitions and the association of such *thresholds* of blood sugar values to neurophysiological properties, hormonal mechanisms or neurodevelopmental outcomes are poorly reproducible.

Hence, it is difficult to identify any particular levels of plasma glucose values that define *pathologic hypoglycemia*. In the absence of unanimous definition of hypoglycemia, *operational thresholds* may be a useful guide for clinicians to take appropriate action rather than diagnostic of a disease. However, the operational thresholds are expert consensus, which are not evidence based and there is

no evidence to suggest improved outcomes following operational threshold. Nevertheless, American Academy of Pediatrics (AAP) recommends cut-off levels of plasma sugar of 47 mg/dL for all neonates.

## GLUCOSE METABOLISM AND BRAIN INJURY

Glucose and oxygen are the principle substances required for energy production in brain. Glucose supply to the brain is regulated by the plasma glucose concentration through facilitated diffusion via glucose transporter 1 (GLUT-1) and GLUT-3. It gets converted to glucose-6-phosphate (via hexokinase), which enters glycolytic pathway to produce energy [adenosine triphosphate (ATP)]; enters hexose monophosphate (HMP) shunt to produce reducing equivalents (for lipid synthesis and nucleic acid synthesis) and gets converted to glycogen. This glycogen is stored in astrocytes and used for energy production. In situations of low blood glucose levels, the cerebral blood flow increases initially so as to increase glucose supply to the brain. Initial metabolic changes include attempts to preserve cerebral energy status by utilizing alternative fuels and initiation of glycogenolysis. In addition to alternative fuels like lactate and ketone bodies, amino acids may also be alternative substrates, as the concentrations of most amino acids decrease sharply along with increase in brain ammonia levels. The concentration of ammonia increases in proportion to decrease in levels of amino acids. Hence, even early in course of hypoglycemia the consciousness levels may fall despite relative preserved ATP levels. This can explain the dissociation between cerebral energy metabolism and neuronal functions during hypoglycemia in some cases. Nevertheless the newborn brain shows relative resistance towards neuronal injury to hypoglycemia, which may be secondary to relatively lower cerebral energy requirements, increase in cerebral blood flow in early phases of hypoglycemia, increased capacity of neonatal brain to utilize alternative brain fuels and relatively less effect on cardiovascular system due to abundant endogenous carbohydrate stores compared to adults. Ketone bodies are taken up by carrier-mediated transport, metabolized after getting converted to acetyl coenzyme A. The therapeutic role of exogenous ketone bodies in hypoglycemia is not known. Lactate gets oxidized to pyruvate by lactate dehydrogenase which is utilized to produce energy.

With continuation of hypoglycemia, energy deficit occurs in cells. In such conditions, there is failure of energy dependent  $\text{Na}^+$ / $\text{K}^+$ -ATPase which renders neurons to lose their ability to maintain normal ionic gradients; i.e., changes in intracellular  $\text{Ca}^{++}$  and extracellular  $\text{K}^+$  concentration. There is intracellular accumulation of  $\text{Na}^+$  and extracellular accumulation of  $\text{K}^+$  leading to sustained membrane depolarization. Intracellular accumulation of  $\text{Na}^+$  would lead to activation of  $\text{Na}^+/\text{Ca}^{2+}$  exchange system and intracellular  $\text{Ca}^{2+}$  accumulation. This leads to phospholipase activation, release of excitatory amino acids (e.g., aspartate and glutamate) from synaptic nerve endings, increase in reactive oxygen and nitrogen species, cellular injury. With continuing hypoglycemia, changes secondary to hypoxia, ischemia and seizures may add to the insult. These combined effects are of major concern as it increases the chances of brain injury even if individual insults are not of sufficient magnitude to cause injury by themselves.

## Pathological Changes in Hypoglycemic Brain Injury

As hypoglycemia quite often coexists with other morbidities, it is difficult to define exact neuropathology in such newborns. However, the topography of the hypoglycemic brain injury is peculiarly shown to have predilection for parieto-occipital cortex. Less commonly it involves hippocampus, caudate nucleus, and putamen. Primarily neurons are involved in hypoglycemic brain

injury but glia are also affected. Hypoglycemia induces apoptotic cell death oligodendrocyte precursor cells and inhibits their differentiation and myelination. The sequelae of hypoglycemic brain injury include microcephaly, widened sulci and atrophic gyri, diminished cerebral white matter and dilated lateral ventricles.

## EPIDEMIOLOGY

Hypoglycemia is commonly associated with a variety of neonatal illnesses. The incidence of hypoglycemia varies with proportion of term and preterm neonates in the population, intrauterine growth status, type and pattern of feeding, screening timings and methods, sickness level and definition used for the diagnosis of hypoglycemia. Lucas et al. found that among 661 preterm neonates of birth weight less than 1850 g, 66% had at least one value of blood glucose less than 2.6 mmol/L ( $< 45$  mg/dL approximately) and 28% had at least one value less than 1.6 mmol/L ( $< 30$  mg/dL approximately). In a study from New Delhi, 107 (7%) neonates were found to have hypoglycemia (cut-off blood sugar  $< 30$  mg/dL) among 2,248 neonates of all gestational ages. The incidence among all preterm neonates was 12.8%. The maximum incidence was noted among small or large for gestation preterm neonates as 20.6 and 21.7%. Similarly among 92 neonates weighing less than or equal to 1,750 g at birth, incidence of hypoglycemia was found to be 26% in a study from Chandigarh.

## CLINICAL FEATURES

The clinical manifestations of hypoglycemia are predominantly nonspecific and related to central nervous system. Commonly hypoglycemia in neonates present with jitteriness, irritability, varying degree of depressed consciousness, seizures, apnea, tachypnea and hypotonia. Singhal et al. have found that among 43 symptomatic neonates out of a cohort of 2248, lethargy was most common symptom (81%), followed by jitteriness (67%), apnea or tachypnea (42%), hypotonia (40%), seizures (30%), and circumoral cyanosis (19%). It is important to realize that hypoglycemia can be asymptomatic. Singhal et al. have found proportion of asymptomatic neonates as 60% among 107 neonates with hypoglycemia.

Based on the clinical setting of hypoglycemia, time and severity of presentation, the neonates with *symptomatic hypoglycemia* can be classified into four categories:

1. *Early transitional adaptive hypoglycemia*: This form manifests in first 6–12 hours of life, after sudden cessation of maternal blood supply. Such neonates fail to mount appropriate metabolic adaptive responses in immediate postnatal life. It is seen that glycolytic and gluconeogenic responses of the neonate are blunted and insulin secretion increases in immediate postnatal life if the mother receives excess glucose in intravenous fluids during intrapartum period. Additional risk factors include neonates who experience hypothermia or asphyxia, large for gestational age infants born to diabetic [infant of diabetic mother (IDM)] or nondiabetic mothers. This form of hypoglycemia lasts briefly, and is mild in severity. The response to treatment is good but the ultimate prognosis depends mainly on the underlying cause.
2. *Secondary associated hypoglycemia*: This form is associated with illnesses other than hypoglycemia particularly involving central nervous system, e.g., birth asphyxia, intracranial hemorrhage; congenital anomalies and other systemic disorders. This variety of hypoglycemia also remains for short duration, is mild in severity and responds rapidly to treatment.
3. *Classic transient neonatal hypoglycemia*: This group predominantly consists of small for gestation term infants, who may concomitantly have polycythemia. The hypoglycemia

manifests in later part of first day. This variety of hypoglycemia is generally moderate to severe, of prolonged duration and often requires high glucose infusion rates.

4. **Severe recurrent hypoglycemia:** This variety is characterized by recurrent or persistent hypoglycemia which occurs in term appropriate for gestational age neonates with endocrinopathies or hereditary metabolic defects. The hypoglycemia is usually severe and is difficult to treat. Neonates are invariably symptomatic. The prognosis depends on the timely detection, appropriateness of therapy and underlying cause.

## MONITORING OF BLOOD GLUCOSE

All preterm and small for date neonates have decreased body stores of glycogen; are associated with other illnesses and hence require blood glucose screening to detect hypoglycemia. Neonates born to mothers with diabetes especially IDM neonates and many large for gestation age infants have excess insulin secretion in the immediate neonatal period, which makes them vulnerable for harmful effects of hypoglycemia. Apart from these neonates, all *unwell* neonates should be monitored for hypoglycemia. Common indications of monitoring blood glucose in newborns are shown in **Table 1**.

### When to Screen 'At-Risk' Neonates?

The neonates, who are predisposed for higher insulin levels, become symptomatic very early in postnatal life. Due to raised levels of insulin, the alternative fuels (ketone bodies and lactate) are less in such neonates, making them even more vulnerable to harmful effects of hypoglycemia. Hence, IDM and severely intrauterine growth retarded neonates deserve screening right from cord blood. This should be followed by the routine screening in the postnatal life for initial 48 hours. Preterm and neonates with intrauterine growth restriction, who are *at risk* should get initial screening within 1 hour of life. All neonates who are symptomatic should be immediately screened get blood glucose levels checked immediately. Screening the asymptomatic at-risk neonates should be performed within the first hours of birth. Standard textbooks and guidelines recommend blood glucose monitoring at 1 hour, 2 hours, 3 hours, 6 hours and then 6 hourly till 48–72 hours by when feeding is likely to be established. Blood glucose should be checked immediately prior to feed, as the screening should be able to identify lowest blood glucose levels.

### Methods of Blood/Plasma Sugar Estimation

An ideal method of blood glucose determination is by laboratory estimation. There are three enzymatic methods namely glucose oxidase, hexokinase, and dehydrogenase method. Plasma glucose measurements are 10–18% higher than blood glucose values. However, the results are not available quickly while using laboratory methods and hence these methods are not very useful for a bedside physician in a symptomatic neonate. At bedside, the

blood glucose measurements are performed with the help of point-of-care glucose meters. The results are available within few seconds and as small as 0.3  $\mu$ L blood sample is required. Hence, all over the world point of care glucometer devices are used for routine measurements, for taking treatment decisions. Glucose values given by point-of-care devices or glucometer might vary from the actual laboratory values by as much as 10–20 mg/dL. These glucometers devices have greatest variation at low glucose concentrations. Due to these limitations the low values by glucometer devices must be confirmed by laboratory methods. Care should be taken to draw the sample in a *glycolytic inhibitor* like fluoride, else the glucose values might be falsely low due to ongoing glycolysis in the sample. Treatment of suspected hypoglycemia should not be postponed awaiting laboratory confirmation as the delay in initiating management might result in hypoglycemic brain injury. However, the scientific evidence showing mitigation of neurologic sequelae by such rapid treatment is also lacking.

One should be aware that some biological parameters might also influence blood glucose values. These include metabolic acidosis, hypoxia, hypoperfusion, or edema. Glucose oxidase method might give abnormally low values at high blood oxygen levels. High hematocrit levels might display falsely low levels. Red blood corpuscles contain proportionally less water than plasma. This problem can be taken care by estimating plasma glucose rather than whole blood. High bilirubin levels may interfere with some analyzers. The glucose concentration in arterial blood is slightly higher than capillary which in turn is slightly higher than venous blood, although the differences are not clinically significant. However, these changes might be relevant if tissue glucose demands increases, e.g., under anaerobic conditions. Blood glucose values, in capillary blood in setting of peripheral circulatory failure, are unreliable as the blood flow is reduced. It is important to get a free-flowing sample, as *squeezing* the tissues to get blood causes hemolysis and alters blood glucose values. Use of alcohol antiseptic solutions for skin preparations might contaminate the sample to give erroneously high values. Delay in processing the sample might also give erroneous values due to ongoing glycolysis. Sodium fluoride added to blood inhibits glycolysis; however longer delays should still be avoided as fluoride is not able to completely prevent it. The sample should be deproteinized (e.g., using perchloric acid) and chilled to avoid glycolysis in such cases. Deproteinization also reduces the interference with hemolysates, uric acid, and bilirubin.

In addition to laboratory methods and glucometers, blood gas and electrolyte analyzers can directly measure blood glucose by electrochemical biosensors. Furthermore, now-a-days continuous glucose monitoring is also possible with the help of subcutaneous glucose oxidase-based platinum sensors or microdialysis. The glucose value measured by sensors is averaged for every 5 min and glucose trend is generated. The risks and benefits of such systems need to be fully evaluated before introducing them in routine clinical

**Table 1** Indications of monitoring blood glucose

Maternal indications	Neonatal indications
<ul style="list-style-type: none"> <li>Maternal drug ingestion, e.g., <math>\beta</math>-blockers, oral hypoglycemics, <math>\beta</math>-sympathomimetics</li> <li>Insulin dependent diabetic mothers</li> <li>Gestational diabetic mothers</li> <li>Massively obese mothers</li> <li>Mothers given large amounts of parenteral glucose during labor and delivery</li> <li>Mothers given parenteral glucose too rapidly prior to delivery</li> </ul>	<ul style="list-style-type: none"> <li>Prematurity</li> <li>Small or large for gestational age</li> <li>Hypothermia</li> <li><i>Sick looking or unwell neonate</i></li> <li>Sepsis</li> <li>Hypoxia ischemia</li> <li>Polycythemia</li> <li>Congenital heart diseases</li> <li>Total parenteral nutrition</li> <li>Blood exchange transfusion</li> <li>Suspected inborn errors of metabolism</li> </ul>

practice. These devices are invasive, expensive, need calibration, and are associated with a significant lag time in collection and measurement. Their role is currently restricted in research settings.

## PREVENTION

The most common reason for low blood glucose levels in immediate postnatal life is delay in normal metabolic adaptation after birth. Therefore, breast or enteral feeds should be initiated within half hour of life in appropriately grown term healthy neonates. In preterm infants of less than 32 weeks gestation or those with neonatal morbidities (e.g., asphyxia or respiratory distress) or any illness interfering with enteral nutrition, intravenous dextrose infusions should be started immediately after stabilization. Glucose delivery in intravenous infusions should correlate with endogenous glucose production. Hence, a glucose infusion rate of 6 mg/kg/min is appropriate for most preterm infants. Wherever there is no contraindication for feeds, an early enteral feeds should always be attempted and gradually increased along with. Late preterm infants of 33–36 weeks gestation require careful nursing to establish enteral feeds due to their physiological handicaps. Expressed breastmilk should always be the first option for enteral nutrition; however supplementary feeds might be needed if breast-feeding is not fully established. The amino acids in enteral feeds might be additional stimulation for gluconeogenesis and hence reduce the duration of intravenous fluids.

## TREATMENT

The management in cases of neonatal hypoglycemia should account for the overall metabolic and physiologic status of the neonate. One should avoid unnecessarily disruption of mother-infant relationship and breastfeeding. The intervention for *low* blood glucose levels should be tailored to the clinical scenario and individualized for infant in consideration. For example, a symptomatic neonate with a plasma glucose concentration of less than 40 mg/dL deserves immediate intravenous glucose treatment and further evaluation. On the other hand a breastfed, asymptomatic term neonate may only require frequent feeding and intravenous therapy may be required only for glucose values less than 25 mg/dL (birth to 4 hours of age) or less than 35 mg/dL (4–24 hours of age) (American Academy of Pediatrics recommendations 2011, **Figure 1**). In such cases glucose value should be rechecked 1 hour after feeding. If the repeat blood glucose levels are recorded lower than 25 mg/dL, or lower than 35 mg/dL, respectively, intravenous glucose infusion should be started. No such guidelines are available for preterm neonates less than 34 weeks and a cut-off of 40 mg/dL should be followed in these neonates. All cases of hypoglycemia whether symptomatic or asymptomatic deserves prompt attention and intervention due to risk of neuronal injury. A reasonable (although empirical) cut-off of blood glucose for treating symptomatic infants is 40 mg/dL. Rapid correction in neonatal hypoglycemia can be achieved with glucose *minibolus* (200 mg glucose/kg, 2 mL/kg of 10% dextrose), as this quickly raises the blood glucose concentration. A minibolus must always be followed by intravenous glucose infusion. If the minibolus is not followed by continuous infusion, a rebound hypoglycemia ensues. The glucose infusion should be initiated at an infusion rate of 6–8 mg/kg/min. After initiation of IV dextrose infusion, repeat blood glucose performed within 20–30 min. If the repeat blood sugar is in *hypoglycemic* range then the glucose infusion rate should be hiked in steps of 2 mg/kg/min. This hike should continue every 20 min until the blood glucose values are maintained between 40 mg/dL and 50 mg/dL. After stabilization of blood glucose levels, frequency of monitoring should be decreased to 4–8 hourly preprandial values. Usually the glucose levels are stabilized between 5 mg/kg/min and 8 mg/kg/min glucose infusion. If the glucose infusion is not maintained after 24 hours at this infusion rates, then consideration

should be given to possibility of hyperinsulinemia. A concentration of more than 12.5% glucose can cause injury to peripheral veins, hence a peripherally inserted central catheter line should be placed. While tapering off, the glucose infusion should be slowly tapered by 2 mg/kg/min every 6–12 hourly to avoid wide swings in blood glucose concentrations. In cases where intravenous line is not available, an intramuscular glucagon may act as a temporary measure to raise blood glucose. Side-effects of glucagon include vomiting, diarrhea, and hypokalemia; at high doses it may stimulate insulin release.

## Refractory or Persistent Neonatal Hypoglycemia

Refractory or persistent hypoglycemia is defined as the requirement of a glucose infusion rate more than 12 mg/kg/min to maintain normoglycemia or persisting or hypoglycemia beyond first 5–7 days of life. Although traditionally it is defined beyond 5–7 days of life, recent AAP recommendations suggest considering this diagnosis beyond 24 hours of life if the blood sugar requirements are above 8 mg/kg/min. The causes of refractory or persistent hypoglycemia are related to endocrine or metabolic disturbances (**Table 2**).

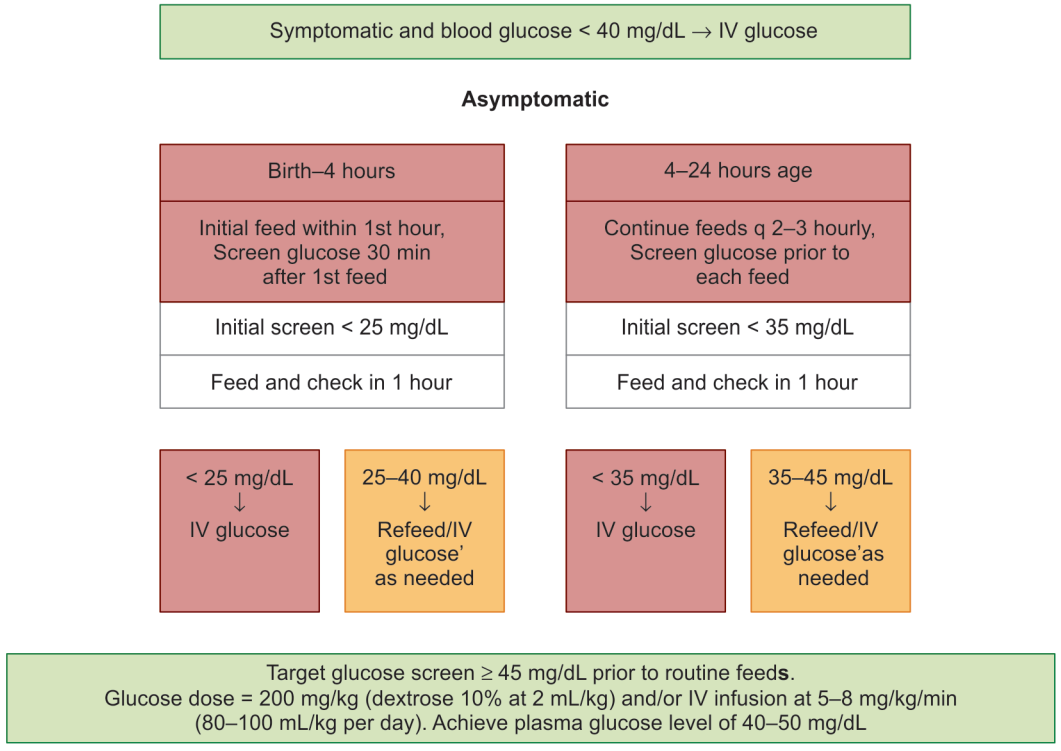

Congenital hyperinsulinism is the most common cause of persistent hypoglycemia, which is also known as persistent hyperinsulinemic hypoglycemia of infancy (PHHI). The diagnosis is confirmed by:

- Hyperinsulinemia (defined as plasma insulin > 2  $\mu$ U/mL), concomitantly with laboratory hypoglycemia (< 50 mg/dL); and/or
- Evidence of excessive insulin effect in form of:
  - Glucose infusion rate more than 8 mg/kg/min
  - Plasma free fatty acids less than 1.5 mmol/L
  - Hypoketonemia (plasma  $\beta$ -hydroxybutyrate < 2.0 mmol/L)
  - Glycemic response (glucose > 30 mg/dL) to 50  $\mu$ g/kg IV glucagon

Insulin levels are relevant only if sample is obtained during hypoglycemia. Insulin-glucose ratio can also be calculated (normal up to 0.2). An elevated insulin-glucose ratio (> 0.4) is found in hyperinsulinemic states. A *normal* or increased level of insulin is considered abnormal if it occurs along with hypoglycemia. PHHI results from elevated secretion of insulin. Due to anabolic effects of insulin, alternative fuels (ketones and lactate) levels decrease and hence newborn brain under such circumstances is particularly vulnerable to hypoglycemic injury. There is a risk of neonatal seizures and neuronal injury if it is left untreated. Hypoglycemia presents early within 72 hours after birth and half of the patients symptomatic hypoglycemia mainly in the form of seizures. The affected neonates may present with other signs of hypoglycemia. Occasionally, hyperinsulinism can be associated with syndromes such as Beckwith-Wiedemann syndrome (BWS), Sotos syndrome, Perlman syndrome, etc.

The treatment should be aggressive due to increased chances of neuronal injury. Invariably these neonates are already on intravenous glucose at the time of diagnosis of hyperinsulinemia. Medical management options include drugs such as diazoxide, nifedipine and octreotide. Diazoxide activates sulfonylurea 1 receptors and blocks insulin secretion. Diazoxide (5–20 mg/kg/day in three divided doses orally) is well tolerated by neonates except in premature neonates. It causes sodium and fluid retention, which may cause edema, heart failure or pulmonary hypertension. Hypertrichosis may occur after prolonged use. Two episodes of hypoglycemia [< 54 mg/dL] occurring in 24-hour period defines diazoxide unresponsiveness. Octreotide (5–25  $\mu$ g/kg/day 6–8 hourly SC injection or IV infusion) must be tried in these cases before considering surgery. Higher doses may suppress both glucagon and growth hormone and worsen hypoglycemia. Transiently some patients may develop vomiting and/or diarrhea and abdominal distension, which spontaneously resolves within 7–10 days. Calcium channels blockers (nifedipine, 0.25–2.5 mg/kg/day in two divided oral doses) can also be tried in such cases. Surgery is considered if medical management is not successful. Patients must be assessed for histological form of

Screening and management of postnatal glucose homeostasis in late preterm and term SGA, IDM/LGA (Late preterm) infants 34–36 weeks, and SGA (screen 0–24 hours); IDM and LGA ≥ 34 weeks (screen 0–24 hours)

hyperinsulinemia beforehand as there are two histological forms (focal and diffuse) of hyperinsulinemia which differ in choice of surgery. Positron emission tomography (PET, 18F-fluoro-L-dopa isotope) can differentiate between the two histological forms. PET has replaced previously employed pancreatic catheterization with pancreatic venous sampling. The focal form, which occurs due to focal adenomatous hyperplasia of islets  $\beta$ -cells within the pancreatic tissue, requires partial and selective pancreatectomy. However, in diffuse form, all the  $\beta$ -cells of the pancreas are abnormal. Hence, subtotal pancreatectomy may improve the patient's condition.

### IN A NUTSHELL

1. Neonatal hypoglycemia is a common metabolic disorder. It can lead to neuronal injury and long-term neurodevelopmental problems.
2. Both asymptomatic and symptomatic forms can cause long-term problems.
3. The operational threshold values of blood glucose  $< 40$  mg/dL (plasma glucose  $< 45$  mg/dL) should be used to guide management. All at risk neonates and all sick neonates should be monitored for hypoglycemia.
4. Screening for hypoglycemia can be done by glucometer devices but confirmation should always be done by laboratory estimation.
5. Treatment should be prompt and should not be delayed while awaiting laboratory confirmation.
6. Asymptomatic hypoglycemia in neonates more than 34 weeks neonates can be managed with a trial of measured oral feeds if blood glucose is less than 25 mg/dL in first 4 hours, or less than 35 mg/dL in 4–24 hours of age and there is no contraindication to feeding. In other neonates or all symptomatic neonates with hypoglycemia, a mini-bolus of 2 mL/kg 10% dextrose should be given followed by continuous infusion of 6–8 mg/kg/min of 10% dextrose.
7. Refractory or persistent hypoglycemia should be suspected and investigated if the glucose infusion requirement is consistently more than 8 mg/kg/min beyond 24 hours or the hypoglycemia persists more than 5–7 days.
8. Babies with hypoglycemia should be followed up for neurodevelopmental sequelae.

## ANEMIA

Hematopoiesis is the process of formation of differentiated blood cells from multipotent stem cells, derived from the yolk sac. There are three phases of hematopoiesis and the site of hematopoiesis changes during each of these phases and in tandem with the maturation of gestational age—the yolk sac from 2nd week to 8th week (mesoblastic phase); liver till 30 weeks (hepatic phase) and bone marrow after that (myeloid phase) (**Fig. 1**). Several growth factors have been implicated in the process of erythropoiesis, the most important among them being the erythropoietin (EPO). At birth with exposure to higher concentrations of oxygen, the newborn undergoes critical changes in erythropoiesis. The hemoglobin concentration can undergo rapid changes making the evaluation of anemia difficult. Various obstetric complications and placental malformations, auto- and allo-immune disorders, failure of bone marrow and defects in the red cell membrane, hemoglobin, and enzymes may all precipitate the onset of anemia early.

## PATHOPHYSIOLOGY

The fetus accretes iron primarily from two sources—maternal iron and destroyed fetal RBCs. Fetal accretion of iron mainly occurs during the last trimester at an average rate of 1.6–2 mg/kg/day, where a term neonate at birth has an iron store of about 75 mg/kg of body weight. This is also reflected in the cord ferritin levels that increases with gestation and is more than 60 µg/L in term neonates. Around 75–85% of the body iron is in the form of hemoglobin within RBC, around 10% as nonhemoglobin proteins (myoglobin, cytochromes), and the remaining 10–15% is stored in the marrow and liver as ferritin and hemosiderin. The factors, which influence the perinatal iron status of the fetus and neonate, are shown in **Box 1**. Babies born to anemic mothers have decreased iron stores and are predisposed to early onset anemia during infancy. Multiple pregnancies increase the iron requirements for the fetus, which the normal iron supplementation may not be sufficient to maintain. As majority of iron accretion occurs in last trimester, preterm babies have decreased stores. Intrauterine growth restriction, although may have higher hematocrit at birth, are prone to early onset anemia after birth due to their higher basal metabolic demands.

**Figure 1** Developmental hematopoiesis and various hemoglobin compositions. Bold lines represent various phases of hematopoiesis, unbold lines represent various types of hemoglobin

## BOX 1 Factors influencing perinatal iron balance in fetus and neonate

### Factors which cause negative iron balance

- **Maternal conditions:** Iron deficiency, smoking, malnutrition
- **Fetal conditions:** Multiple pregnancy, prematurity, IUGR, prematurity, fetomaternal bleeding
- **Neonatal conditions:** Early cord clamping, increased phlebotomy losses, inadequate iron supplements, restrictive transfusion practice, exchange transfusions, infections, exclusive breastfeeding, cow milk feeding

### Factors which cause positive iron balance

- **Maternal conditions:** Iron supplement
- **Fetal conditions:** Multiple pregnancy, prematurity, IUGR, prematurity, fetomaternal bleeding
- **Neonatal conditions:** Delayed cord clamping, decreased phlebotomy losses, adequate postnatal iron supplements, liberal transfusion practice, iron fortified formulas

Abbreviation: IUGR, intrauterine growth retardation.

Delayed cord clamping at birth is one intervention which has been shown to increase ferritin and result in decreased need for blood transfusion in both term and preterm neonates. The distribution of blood in the fetoplacental unit at term is around 40:60 at term between placenta and baby. The placenta contains an even greater blood volume in preterm neonates with the ratio being almost 60:40. The amount of placental transfusion depends on the timing of cord clamping. Around 20–30 mL/kg of baby weight equivalent blood volume can be transfused from the placenta to the neonate by delaying the cord clamping by 45–60s in preterm neonates at birth.

Despite the iron stores bestowed at birth, there are several neonatal factors that predispose a neonate to develop anemia in the postnatal life:

- The rapid phase of postnatal growth and associated increase in extracellular volume and intracellular volume requires expansion of erythropoiesis.
- Decreased survival of RBCs (around 70–90 days as compared to 120 days in adults).
- Decreased EPO levels (erythropoietin becomes negligible after the first week), probably due to increased tissue oxygen delivery.
- Decreased deformability of neonatal RBC, which results in sequestration in splenic sinusoids and destruction.
- Decreased protein intake in postnatal life; neonates with protein intake of 3.5 g/kg/day have hemoglobin 1–1.5 g/dL higher than those with protein intake of 2 g/kg/day.
- Phlebotomy losses. Some have suggested that sampling losses are major cause of anemia in a preterm neonate. Studies have shown that sick preterm neonates may have sampling losses to the extent of 11–22 mL/kg during the first 2 weeks of life.
- Infections are common among the very preterm neonates. As many as 50% of extreme preterm neonates suffer at least one episode of sepsis, and this is higher in developing countries. Sepsis increases erythropoiesis and consumption of iron stores, may result in disseminated intravascular coagulation and blood loss, and suppresses the marrow via cytokine-mediated mechanisms.
- Some neonatal care facilities use recombinant erythropoietin routinely to improve erythropoiesis in very preterm neonates. This increases the iron requirements, which if not provided adequately, can quickly result in deprivation of ferritin stores and result in anemia.

A complex interplay of these factors leads to progressive utilization of the iron stores. In the absence of EPO, erythropoiesis is not stimulated [evident by the reduced reticulocytes (1–3%)]. This state continues till a nadir is reached at about 6–8 weeks in term neonates and about 1–4 weeks earlier in preterm neonates.

This nadir and associated hypoxia triggers the release of EPO and resultant erythropoiesis. In some extreme preterms, this point may be reached as early as 1–2 months, hence the justification for early iron supplements in this population. Although breastmilk contains less amount of iron, but its bioavailability is better. Thus, term babies on exclusive breastfeeding need additional iron supplements after usually 4–5 months.

## ETIOLOGY

Anemia in neonates is primarily due to three basic mechanisms: blood loss, hemolysis and failure of production (**Box 2**). The common causes encountered in the neonate are highlighted in bold.

### Anemia due to Blood Loss

Significant fetomaternal hemorrhage (FMH) occurs in about 8% of pregnancies. This is an important consideration in the neonates who are anemic at birth. It has been estimated that about 40 mL of FMH would be required to present as anemia at birth. FMH can be diagnosed and quantified from the fetal RBCs in the maternal circulation (Kleihauer-Betke test). Rupture of umbilical cord is seen in preterm precipitous deliveries and if not controlled immediately with clamping can exsanguinate the neonate. Postnatal blood loss from sampling is probably the most important cause of anemia in neonatal intensive care unit candidates. Blood loss into various body compartments (cephalohematomas, subgaleal bleed, sub-arachnoid hemorrhage, and hepatic rupture) may occur in traumatic deliveries, instrumentation, and perinatal asphyxia and may result in large amount of blood loss.

#### BOX 2 Etiological factors for anemia in a neonate

##### Blood loss

- **Fetal:** Feto-maternal bleed, twin-twin transfusion, hemorrhage following amniocentesis
- **Placental:** Placenta previa, placental abruption, placental laceration, velamentous cord insertion, accidental placental incision during cesarean section, vasa previa, placental chorioangioma
- **Umbilical:** Cord rupture with precipitous delivery, cord hematoma
- **Neonatal:** Blood collections: cephalohematoma, subgaleal hemorrhage, intracranial bleed; hepatic or splenic rupture; retroperitoneal hemorrhage; blood-letting for investigations

##### Hemolysis

- **Immune:** Rh incompatibility, ABO or minor blood group incompatibility, autoimmune hemolytic anemia, lupus erythematosus
- **Infections:** Bacterial, Viral-CMV, toxoplasma, syphilis, rubella, herpes, malaria, DIC, microangiopathic anemia
- **Red cell membrane disorders:** Hereditary spherocytosis, elliptocytosis, stomatocytosis, pyropoikilocytosis
- **Red cell enzyme deficiencies:** G6PD deficiency, pyruvate kinase deficiency, hexokinase deficiency
- **Hemoglobinopathies:** Alfa thalassemia, gamma thalassemia
- **Miscellaneous:** Hypothyroidism, vitamin E deficiency

##### Failure of production

- **Physiological:** Anemia of the newborn, anemia of prematurity, late anemia of hemolytic disease
- **Constitutional:** Diamond-Blackfan, Shwachman-Diamond, Pearson syndrome, Congenital dyserythropoietic anemia, Fanconi anemia, TAR syndrome
- **Acquired:** Aplastic anemia, infection (CMV, rubella, toxoplasma, bacterial sepsis), anemia associated with bronchopulmonary dysplasia
- **Nutritional:** Iron deficiency, folate deficiency, vitamin B<sub>12</sub>
- **Bone marrow infiltration:** Neuroblastoma, congenital leukemia, storage disorders, histiocytosis

**Abbreviations:** TAR, thrombocytopenia and absent radii; CMV, cytomegalovirus; DIC, disseminated intravascular coagulation; G6PD, glucose-6-phosphate dehydrogenase.

## Hemolytic Anemia

Hemolysis is characterized by increased destruction of RBCs, resulting in progressive anemia and unconjugated hyperbilirubinemia, evidence of extramedullary hematopoiesis in the form of hepatosplenomegaly and in rare circumstances subcutaneous erythropoiesis—*blueberry muffin* like maculopapular lesions. Immune hemolysis is mediated by antibodies, which coat fetal RBCs and result in their sequestration and destruction in the spleen. In Rh incompatibility, the Rh negative mother gets sensitized to Rh positive RBC, which may occur through abortions, fetal diagnostic studies like chorionic villus sampling or amniocentesis, FMH, fetal manipulations like internal or external podalic inversion performed to change an unfavorable presentation of the fetus, as well as during exposure to Rh positive cells during mismatched blood transfusion. The prevalence of this condition has been estimated to be about 385/100,000 births in South Asia as compared to 2.5/100,000 births in developed countries. ABO incompatibility is usually a mild disease, with less than 10% of affected babies manifesting clinically with jaundice and anemia. Glucose-6-phosphate dehydrogenase (G6PD) deficiency is another important cause of anemia during infancy. The prevalence of this condition is estimated at less than 20% for the South Asian region. However, there is a wide regional variation within our country, with Northern part of the country having prevalence of 15–20%, while the Southern states having prevalence of less than 5%. G6PD deficiency predominantly presents in the neonatal period as severe hyperbilirubinemia or prolonged jaundice. Alpha thalassemia usually causes hydrops and in utero demise, however, cases presenting in neonatal period are known. Intrauterine infections causing anemia usually are associated with other clinical manifestations such as growth retardation, microcephaly, bleeding tendency, cardiac disease, jaundice, etc., which help in diagnosis.

## Hypoplastic Anemia

These are among the rarer causes of anemia in the neonate. These usually do not present at birth as the neonatal RBCs have a survival of around 2 months, after which period they usually manifest. The characteristic hallmark is the reticulocytopenia despite severe anemia. The majority of hypoplastic anemia cases are due to acquired conditions and infections. Mechanisms involved are cytokine-mediated suppression of normal erythropoiesis and direct damage to progenitor cells. However, few primary congenital hypoplastic anemia can present in early infancy such as transient erythroblastopenia of infancy, which is the most common variety, and is characterized by anemia, reticulocytopenia, and resolves spontaneously by 1 year of age.

## CLINICAL FEATURES

Clinical features of anemia in a neonate (**Table 1**) depend on the following factors—duration over which anemia has developed, severity of anemia, and postnatal age at presentation. Acute anemia is most commonly due to significant amount of blood loss and may present with circulatory compromise, sudden collapse and listlessness, limpness, and signs of respiratory failure such as gasping respiratory efforts or apnea. It is important to remember that due to equal volume of plasma loss, the hemoglobin and hematocrit remains unchanged till initial 4–6 hours period of gradual hemodilution. Thus, acute blood loss is one clinical condition where blood needs to be transfused despite normal or near normal hematocrit values. Reticulocytosis ensues after 2–3 days which heralds compensatory bone marrow hyperplasia. On the other hand, fetus and neonates usually adequately compensate chronic blood loss and does not result in a catastrophic event. However, it results in growth failure and decreased basal

**Table 1** Clinical manifestations of anemia in a neonate

<i>Effects on the fetus</i>	<i>Acute anemia</i>	<i>Chronic/long standing anemia</i>
Fetal growth retardation (FGR)	Moderate to severe pallor	Pallor
Hydrops fetalis	Hypotension	Metabolic acidosis
Congestive cardiac failure	Collapse, coma	Reduced activity, poor feeding
Intrauterine fetal demise	Gasping respiration or Respiratory failure	Poor physical growth
	Seizures	Congestive cardiac failure – tachypnea, tachycardia, hepatomegaly, edema
		Apnea
		Oxygen requirement

**Table 2** Normal values of various hematological indices in newborns and infants

<i>Age</i>	<i>RBC (million/uL)</i>	<i>Hemoglobin (g/dL)</i>	<i>Hematocrit (%)</i>	<i>MCV (fL)</i>	<i>MCH (pg/g)</i>	<i>MCHC (%)</i>	<i>RDW</i>
0–3 days	4.0–5.9	14.5–20.5	45–61	95–115	31–37	29–37	< 18
4–9 days	3.9–5.7	13.5–19.5	42–60	88–112	28–36	28–38	< 18
10–14 days	3.6–5.5	12.5–18.5	39–57	86–110	28–36	28–38	< 17
15–30 days	3.0–4.8	10.0–16.0	31–49	85–108	26–34	30–36	< 17
1–6 months	3.0–4.3	9.5–12.9	29–42	74–96	25–35	30–36	< 16.5
7–24 months	3.7–4.9	10.5–12.8	33–38	70–84	23–30	31–37	< 16

*Abbreviations:* RBC, red blood cell; MCV, mean corpuscular volume; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; RDW, red cell distribution width.

metabolic rate manifesting as poor feeding and lethargy to cut down energy expenditure. If this continues uncorrected, it may result in a state of high output cardiac failure.

Symptoms of anemia that suggest inadequate tissue oxygenation are an increase in oxygen requirement, tachycardia, apnea, and poor weight gain. However, these indicators nonspecific and do not correlate well to hemoglobin levels or respond consistently to RBC transfusions.

## EVALUATION OF ANEMIA

Definition of anemia should ideally involve erythrocyte mass measurement, the best measure of anemia. In adults, it correlates directly with hemoglobin values, which can be used as a valid means of determining anemia. However, in infants, the correlation between erythrocyte mass and hemoglobin values is poor and extremely wide variations in the erythrocyte mass values for any given hematocrit values have been observed. Moreover, capillary hematocrit is often a poor reflection of the circulating erythrocyte mass in newborn infants. This is particularly true in ill infants, in whom a poor peripheral circulation may exaggerate capillary and venous hematocrit differences. For all practical purposes, hemoglobin or a hematocrit value measured from a venous blood sample should be the ideal sample for defining and monitoring anemia (**Table 2**).

The general approach to anemia in a neonate is based on the same principles used in the evaluation of older children (**Table 3**). The most important question that comes to the mind is whether the low hemoglobin level is due to decreased RBC production, shortened RBC survival or a combination of these two processes. Blood loss is another important consideration for anemia in neonates, especially preterm neonates. This classic approach is however complicated by a hemoglobin concentration that undergoes constant physiologic change during the first few weeks of life (**Table 2**). Moreover, source of blood and site of sampling can also influence the hemoglobin levels in neonates—capillary samples can vary as large as 1.5 g/dL from the true hemoglobin levels and can also be significantly higher than the venous blood sample values (see above).

It is important to first determine whether the low hemoglobin level can be explained by blood loss from sampling. Cumulative losses, particularly in ill preterm neonates, may be extremely large, and correct interpretation of rapid changes in hemoglobin level can be made only if careful attention is paid to the exact volumes blood sampled and transfused. Anemia resulting from decreased RBC production develops slowly allowing physiologic compensation. Consequently the infant may be having surprisingly few clinical signs of anemia other than pallor. In contrast, a newborn with anemia caused by RBC destruction or acute blood loss often appears acutely ill. Hemolytic anemia usually is accompanied by jaundice and less frequently, enlargement of spleen. The reticulocyte count is elevated and nucleated RBCs may persist in the peripheral blood beyond the first few days of life. Additional laboratory tests can be added once the distinction between decreased RBC production and shortened RBC survival is made. If hemolysis is suspected, additional work-up towards a specific diagnosis such as hemoglobin electrophoresis for hemoglobin H or measurement of enzyme levels for erythrocyte metabolic abnormalities may be planned.

The efficiency of the diagnostic search can be greatly enhanced by *detailed maternal and family history*. The history of febrile illness with rash in mid pregnancy should prompt early investigation for a viral origin for neonatal anemia. A history of several family members with neonatal jaundice and anemia cured by splenectomy should direct the investigation towards membrane disorders such as spherocytosis. Age at anemia is first noticed is also of diagnostic value. Marked anemia at birth is usually due to hemorrhage or severe alloimmunization. Anemia manifesting itself in the first 2 days of life is usually due to external or internal hemorrhages, but anemia appearing after 48 hours of life is usually hemolytic and more commonly is associated with jaundice.

Apart from history, *general physical examination* can many times yield important diagnostic clues. For example, infection associated anemia is usually associated with other abnormalities of the primary disorder, which can be identified on examination and can offer clues to diagnosis. Additionally, severity of anemia should be thoroughly assessed before planning for detailed evaluation.

A well-term neonate with venous hemoglobin of 14.5 g/dL is unlikely to have a serious hematologic disorder and the collection of numerous blood samples for a variety of investigations would lead to sampling loss and further decrease in hemoglobin without improving the overall diagnostic yield.

The clinician must tailor the *investigations* and do them in a proper order that takes him/her towards the diagnosis. Moreover, neonatal hematological indices vary from children and adult values as well as on different postnatal age and these must be kept in mind while interpreting tests (**Table 2**). A proposal of different tiers of investigations to approach anemia in a neonate has been described below, and a flow diagram for approach is given in **Flow chart 1**.

*Tier 1:*

- Hemoglobin, hematocrit, peripheral blood smear examination, reticulocyte count
- *RBC indices:* Mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), red cell distribution width (RCDW)
- Glucose-6-phosphate dehydrogenase (G6PD) deficiency
- Blood group, direct antiglobulin test (DAT)
- Total and conjugated fraction of serum bilirubin (in the presence of jaundice).

*Tier 2:*

- TORCH group of infections: paired mother infant serology
- Kleihauer-Betke test (KBT), Apt-Downey test
- *Sepsis work-up:* TLC, ANC, CRP, Blood and CSF cultures
- *Imaging:* Intracranial bleed, intracranial calcifications, hydrocephalus, intraperitoneal bleed
- *Intravascular hemolysis:* Plasma and urine hemoglobin.

*Tier 3: Rare etiologies*

- Hemoglobin electrophoresis
- *Bone marrow aspiration:* Hypoplastic anemia, storage disorders
- Vitamin E levels

*Miscellaneous:*

- *Iron studies:* Ferritin, transferrin saturation, protoporphyrin levels, serum iron, Iron binding capacity
- *Advanced imaging:* Cardiac and liver iron stores
- *Near infrared spectroscopy:* Cerebral oxygenation.

## SPECIAL NOTE ABOUT FEW INVESTIGATIONS

### Complete Hemogram

The peripheral blood picture in neonates is difficult to interpret as anisopoikilocytosis (different sizes and shapes of RBCs) are normally seen as are schistocytes and burr cells. However, presence of certain forms such as spherocytes (seen in hereditary spherocytosis, ABO incompatibility), Heinz bodies and bite cells (seen in G6PD deficiency, thalassemia) are reasonably specific. RBC indices provide clues such as whether the clinician is dealing with microcytic hypochromic anemia or a normocytic anemia, the causes of which are different, as shown later in the algorithm. The normal values of hematological indices in various age groups are given in **Table 2**.

### G6PD Deficiency Status

The prevalence of G6PD deficiency varies across different states and this test must be considered as a tier 1 investigation in regions with high prevalence. It is done in whole blood and dye reduction tests are used. However, it must be borne in mind that G6PD is a function of the age of the RBCs. During active hemolysis, the peripheral blood may contain majority of younger erythrocytes (neocytes), which may show an intermediate or even a normal G6PD enzyme levels. Hence, in cases where it is strongly suspected, it is recommended that the test may be repeated after about 2–3 months.

### Direct Antiglobulin Test

This test is used to detect antibody coated RBCs, which is a marker of immune hemolytic anemia. The test is performed in whole blood; the RBCs are washed to remove the plasma; mixed with antihuman globulin and if RBCs are coated with antibodies, they aggregate. However, this test may give false negatives if the antibody titer is very high (pro-zone phenomenon). In such cases, the test may be repeated with serial dilutions to negate the effect of antibody excess.

### Kleihauer-Betke Test

This test is performed on maternal blood to identify fetal erythrocytes and is used to detect FMH. It takes advantage of the differential resistance of fetal hemoglobin to acid elution. A standard blood smear is prepared from the maternal blood and stained with citric acid-phosphate buffer, which denatures the adult hemoglobin selectively. Subsequent staining with Shepard's method stains the fetal hemoglobin rose pink color, while the maternal RBCs are seen as ghost cells with eluted hemoglobin. Quantification can be made as to the amount of FMH. For this, the smear prepared is viewed, the fetal and adult RBCs are counted till a total of 2,000 cells are counted. Percent of fetal RBCs are given by  $[(\text{Fetal RBC})/(\text{Total RBC counted (2000)}) \times 100]$ . The amount of FMH is calculated by multiplying the percent of fetal RBC's by 50 (considering maternal blood volume as 5000 mL). For example, if in total 2,150 RBCs counted, there are 20 fetal RBCs, the percent of fetal RBCs will be 0.9, and the amount of FMH will be around 45 mL. The test needs to be performed soon after birth as with advancing time and with small quantities of fetal blood seeped in to the maternal circulation, the fetal cells may be cleared from maternal circulation.

### Apt and Downey Test

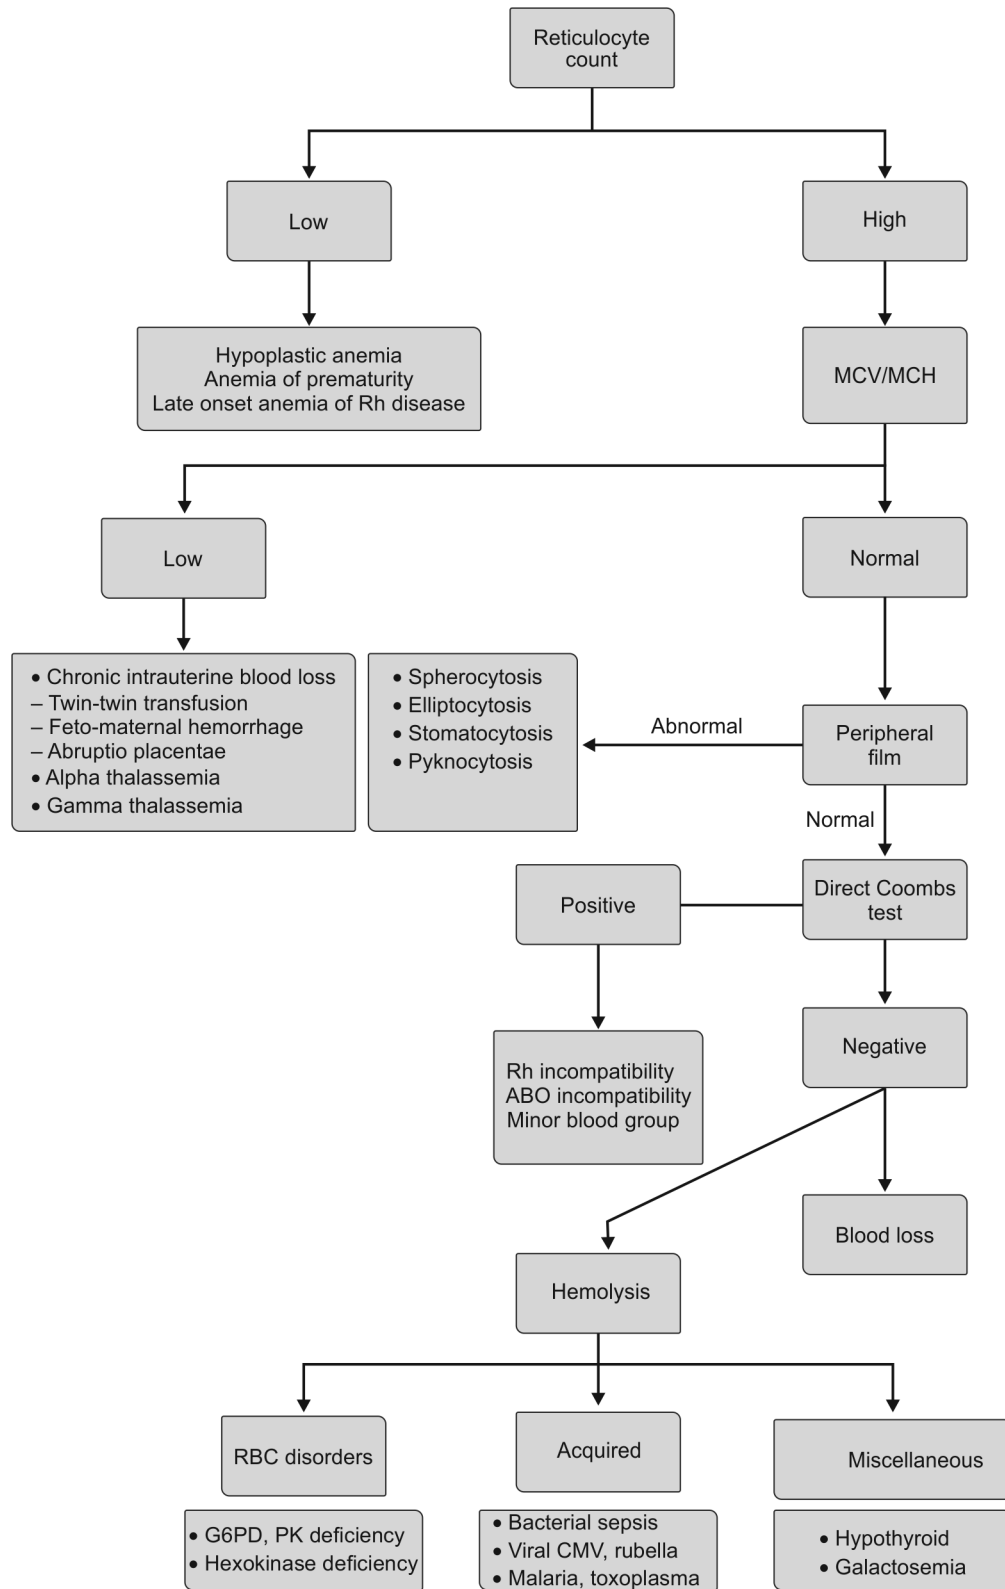

Occasionally an infant may have gastrointestinal bleeding associated with anemia. If this happens close to delivery, it is essential to differentiate this from swallowed maternal blood during delivery. Apt and Downey test is based on the resistance of fetal hemoglobin to alkali denaturation. The principle is similar to KBT in that after alkali treatment, the survived fetal hemoglobin gives a pink color while the denatured maternal hemoglobin gives a yellow brown color. This however, is only a qualitative test.

### Iron Studies

The major disadvantage of using hemoglobin and hematocrit is that they are affected much late; by which time the body iron stores would have significantly reduced. Reticulocyte count is also highly variable, especially during the initial few days, and peripheral blood picture as stated can normally have many abnormal looking cells.

- *Ferritin:* Around 10–15% of iron in the body is stored as ferritin and hemosiderin, primarily in the bone marrow and liver. A small fraction of this is detected in the plasma, the concentration of which is proportional to the body iron store. Around 1 mL of blood needs to be collected in EDTA or heparinated vial. The test can be performed on serum as well as plasma. The samples need to be stored at 2–8°C for shorter use. However, they can be stored at -20°C for 6–9 months and at -80°C till 3 years. The normal values in various age groups are as follows; Neonates 25–200 µg/L, 1–5 months 50–200 µg/L, 6 month–15 years 7–140 µg/L.
- Similarly other tests such as serum iron, total iron binding capacity, transferrin saturation give a better estimate of body's iron status and efficiency of erythropoiesis. However, these tests are not very sensitive during the perinatal period and hence are not used routinely.

**Flow chart 1** Algorithmic approach to anemia in the neonate

## MANAGEMENT OF ANEMIA

The modalities used in the management of anemia include blood transfusion; iron supplementation; erythropoietin therapy; and immunoglobulin for immune hemolytic anemia.

### Blood Transfusion

Blood transfusion is one of the important modalities for acute management of anemia in neonates. However, transfusion of blood has been implicated as the reason for various complications, possibly due to the oxidative stress, increased viscosity and yet to be identified immune dysregulation related factors that put the newborn at risk. Recently described entities like transfusion associated lung injury (TRALI) and transfusion associated necrotizing enterocolitis (TRANEC) are serious complications, if proven, would lead to even more stringent use of blood products. While deciding to transfuse whole blood or packed red cells, the following aspects have to be considered—when to transfuse, how much to transfuse, how fast to transfuse, blood requirements, technique of transfusion and how to assess the response.

### When to Transfuse

The transfusion need has traditionally been related to hemoglobin/hematocrit (Hct) values in relation to the reference ranges of hemoglobin or Hct at different postnatal ages, and to the clinical status of the newborn. Clinical indicators are nonspecific and do not correlate well with hemoglobin levels or respond consistently to RBC transfusions. Absence of ready availability of biochemical parameters as well as inconsistent evidence favoring them makes them less attractive assessment indicators. Hence, it is recommended that hemoglobin or Hct levels form the primary indicators for deciding the need of pRBC transfusion (**Table 4**). However, decision-making has to take into consideration the clinical status of the newborn such as presence of severe cardiovascular diseases, or symptoms of anemia.

### How Much and how Fast to Transfuse?

Most infants are transfused 10 or 15 mL/kg of pRBCs, depending upon the cardiovascular status. Packed red cells contain 2 mL RBCs in every 3 mL volume. Hence, every 10 mL/kg of pRBC transfusion

**Table 4** Guidelines for blood transfusion in anemia in neonates

<b>Group A: Asymptomatic</b>	Hct $\leq$ 20%; reticulocytes $<$ 100000/ $\mu$ L
<b>Group B:</b> <ul style="list-style-type: none"> <li>• Weight gain <math>&lt;</math> 10 g/day while receiving <math>\geq</math> 100 kcal/kg/day</li> <li>• Significant apnea or bradycardia</li> <li>• Tachypnea or tachycardia</li> <li>• <math>&lt;</math> 35% hood oxygen with CPAP/IMV with Paw <math>&lt;</math> 6 cm H<sub>2</sub>O</li> <li>• Surgery</li> </ul>	Hct $\leq$ 30%
<b>Group C:</b> <ul style="list-style-type: none"> <li>• <math>&gt;</math> 35% hood oxygen</li> <li>• CPAP/IMV with Paw <math>\geq</math> 6–8 cm H<sub>2</sub>O</li> </ul>	

results in a hemoglobin rise of about 3 g/dL and a hematocrit rise of about 10%. Small volume pRBC aliquots may be transfused without warming particularly if the transfusion is given slowly over two to three hours. A controlled blood warmer should be used for large volume transfusions, particularly exchange transfusions. All blood components must be filtered before transfusion. The standard 120–170  $\mu$  pore-size filter is adequate for red cells, plasma, and platelets. Third-generation leukodepletion filters with “ultra-filtration” capability of removing 99.9% of white blood cells by mechanical sieving and cell adhesion have been recommended to decrease transmission of cytomegalovirus and other viruses harbored in leukocytes and to decrease the incidence of alloimmunization. Leukodepletion preferably should be carried out in the laboratory within a few hours of blood collection, rather than by using bedside filters.

### Partial Exchange Transfusion (PET)

PET using packed RBCs is used to correct severe anemia and improve oxygenation in critically ill hydropic infants with severe HDN until they can be stabilized sufficiently to undergo a complete double-volume exchange transfusion. In cases of anemia, a modified calculation would be helpful.

$[(\text{Desired} - \text{Patient Hct}) / (\text{pRBC} - \text{Patient Hct})] \times \text{weight (kg)} \times \text{blood volume (80–100 mL/kg)}$

Hct – hematocrit, pRBC – packed RBC

### Iron Therapy

Term neonates have sufficient iron stores to sustain erythropoiesis for 4–6 months. However, preterm neonates are at risk for early iron deficiency. Although stores are sufficient for first 2 months, however, early enteral iron supplementation starting at around 2 weeks of age, with a dose of 2–3 mg/kg daily has been shown to improve their RBC indices and iron stores measured by ferritin at 6 months of age and the effect persisted till 12 months. The current American Academy of Pediatrics (AAP) recommendation is to begin iron supplementation in all breastfed full-term infants at 4–6 months through iron-containing complementary foods. If iron cannot be provided through dietary sources, elemental iron at 1 mg/kg/day should be used after 6 months.

### Erythropoietin

Erythropoietin (EPO) can be given *early* (before the infant reaches eight days of age) or *late* in order to prevent or decrease the use of pRBC transfusions. The benefit of exogenous EPO to stimulate RBC production and overcome anemia of prematurity is still being debated, despite numerous multicenter trials. Given the

current evidence, neither *early* nor *late* rEPO can be routinely recommended for preterm infants.

### Placental Transfusion for Autologous Transfusion

Delaying cord clamping from 60s to 3 min, milking/stripping the cord and holding the newly born infant well below the vaginal introitus/placenta immediately after delivery of the baby but before the expulsion of the placenta has been shown to reduce the need for blood transfusion and improve the iron stores at 6 months of age. Hence, delaying cord clamping at least up to 60s from the birth of the baby is currently recommended in term neonates considering its short-term benefits.

### Intravenous Immunoglobulin

Immune hemolysis due to Rh and ABO blood group incompatibilities may be reduced and prevented by using intravenous administration of IVIG. Even though the mechanisms by which immunoglobulin prevent hemolysis are unclear, it seems to reduce hemolysis by competitively binding with the splenic site and preventing extravascular hemolysis. Conventionally it is administered in a dose ranging from 400 g to 1000 g/kg body weight. Even though many previous studies reported that Ig administration is beneficial, a recent meta-analysis showed no benefit of Ig therapy in Rh hemolytic disease, either in preventing exchange transfusions or reducing the peak serum bilirubin, especially following a sensitivity analysis of studies with a low risk of bias. Hence, administration of Ig for immune hemolysis should be considered on a case-by-case basis till further evidence comes in.

## POLYCYTHEMIA

The incidence of polycythemia varies from 1–5% of all infants born at term. The incidence varies based on the definition of polycythemia and hyperviscosity, which in turn have varied based on the source of blood sample and the age of the infant at the time of measurement. In many studies, a hematocrit value of 65% and above has been diagnostic for polycythemia. Based on population data from many sources, it has now been accepted that polycythemia should be defined as a hematocrit value of  $\geq$  65% from a large, freely flowing peripheral vein. *Hyperviscosity* has been defined as a value of more than two standard deviations from the mean. Viscosity, as defined by Poiseuille, is the ratio of shear stress to shear rate, as demonstrated by the formula:

$$\eta = (p-p')r^4 \pi / 8lQ = \text{shear stress/shear rate}$$

$\eta$  is blood viscosity (dynes/s/cm<sup>2</sup>),  $p-p'$  is the pressure gradient along the blood vessel,  $r$  is the radius,  $l$  is the length of the blood vessel and  $Q$  is blood flow.

### PATHOGENESIS

Several factors influence the hematocrit of the neonate in the perinatal period (**Table 5**). Placental transfusion at birth, i.e., transfer of blood from the placenta to the baby has been shown to increase both the infant blood volume and the RBC volume. Placental transfusion can be achieved by delaying cord clamping after the birth of the baby. Studies have shown that a delay of 60 sec to 180 sec results in an additional transfer of blood of 20–30 mL/kg equivalent of infants body weight. Others have also shown an increase in RBC volume in preterm infants below 35 weeks gestation. However, none of these studies have shown that placental transfusion per se leads to polycythemia; even though this factor in combination with the other above-mentioned factors can increase the risk of polycythemia. The other factor, which determines the neonatal hematocrit, is intrauterine hypoxia. Both acute as well as

**Table 5** Factors that predispose polycythemia and hyperviscosity

<i>Polycythemia</i>	<i>Hyperviscosity</i>
<ul style="list-style-type: none"> <li>• Timing of cord clamping</li> <li>• Distance of baby below the vaginal introitus at birth</li> <li>• Intrauterine growth</li> <li>• Fetal hypoxia</li> <li>• Site of sampling</li> <li>• Postnatal age</li> <li>• Altitude</li> </ul>	<ul style="list-style-type: none"> <li>• Hematocrit</li> <li>• Red cell deformity</li> <li>• White blood cells—size and deformity</li> <li>• Vessel size—capillaries &gt; arteries &gt; great arteries</li> <li>• Blood pH—increases with blood pH &lt; 7.00</li> <li>• Fibrinogen, platelets and plasma proteins—less contribution</li> </ul>

chronic hypoxias have been shown to result in higher hematocrits at birth. Acute hypoxia results in placental transfusion, the volume of which is proportionate to the duration the stay of the fetus in utero. On the other hand, chronic hypoxia results in an increase in erythropoiesis in the fetus and thus elevates the hematocrit values. For similar reasons, babies born at higher altitude have higher hematocrits.

The hematocrit of the neonate increases soon after birth due to shifting of intravascular volume to the extravascular space during delivery. The peak value is reached around 4–6 hours after birth. Thereafter, due to resifting of fluid into the intravascular space from the interstitial space, the hematocrit reaches its birth value around 12–24 hours of life and thereafter remains stable. The sampling site can also affect the hematocrit values. In studies comparing three sites, capillary, peripheral venous and umbilical venous, the highest hematocrits were observed with capillary blood followed by peripheral venous and umbilical venous blood. Dehydration, by decreasing the plasma volume, can also result in hemoconcentration and polycythemia.

## ETIOLOGY

There are three major categories of etiologies or clinical scenarios in which polycythemia and hyperviscosity may be observed (**Box 3**). These include chronic fetal hypoxia, acute fetal hypoxia/asphyxia and delayed cord clamping at birth. Other less common causes and associations include maternal-fetal hemorrhage, fetofetal transfusion and chromosomal abnormalities.

## CLINICAL FEATURES

The hyperviscosity associated with polycythemia results in decreased organ blood flow, especially to vital organs and leads to increased oxygen extraction to maintain tissue oxygenation. The symptoms of polycythemia depend upon the severity of hyperviscosity, organ blood flow, etiology of polycythemia, and associated clinical conditions. For instance, a small for gestational age (SGA) infant with perinatal asphyxia may have polycythemia; however, several of the clinical manifestations can be explained by either SGA or polycythemia or asphyxia or their combination. This dilemma daunts the clinician and is important to consider if partial exchange is to be undertaken, as symptoms may not improve in such scenario.

The clinical manifestations of polycythemia are variable (**Box 4**). One author reported that cyanosis, plethora, tremulousness, hyperbilirubinemia and abnormal blood smear examination as the most common manifestations of polycythemia. Another author reported plethora and lethargy/poor feeding as common manifestations of polycythemia. However, a large majority of neonates were asymptomatic despite being diagnosed as polycythemic, underscoring the importance of routine monitoring in high-risk neonates to identify such neonates. The hyperviscosity results in elevation of pulmonary resistance and intrapulmonary

### BOX 3 Etiologies and associations of polycythemia

Acute hypoxia—perinatal asphyxia

Chronic hypoxia

- Maternal pre-eclampsia
- Infant of diabetic mother
- Intrauterine growth restriction
- Neonatal thyrotoxicosis
- Placental insufficiency
- High altitude
- Maternal smoking

Delayed cord clamping

Intrauterine transfusion

- Maternal-fetal
- Feto-fetal

Syndromes

- Trisomy 13,18,21
- Beckwith-Wiedemann syndrome

### BOX 4 Common clinical manifestations of polycythemia and their frequencies

- Cyanosis (89%)
- Plethora (63–83%)
- Cardiomegaly (85%)
- Tremulousness/jittery (67%)
- Lethargy/poor feeding (55%)
- Thrombocytopenia (25–40%)
- Hypoglycemia (27–40%)
- Respiratory distress (25%)

shunting, resulting in cyanosis, tachypnea and plethora on chest X-ray. Although cardiomegaly may be seen, it is not clear whether it is primarily due to polycythemia or due to associated complication like hypoxia/asphyxia. Hyperviscosity may also lead to a decrease in splanchnic blood flow and intestinal ischemia and increase the risk of necrotizing enterocolitis (NEC). Another important concern with polycythemia is reduction in cerebral blood flow and its long-term consequences. Many reports have associated symptoms like poor feeding, lethargy, tremors and seizures to polycythemia and hyperviscosity. However, there is no evidence as of now that treatment of polycythemia leads to reduction or prevention from such symptoms. Hypoglycemia is another manifestation of polycythemia and probably is due to the increased glucose consumption due to increased RBC mass.

## MANAGEMENT

Management of polycythemia includes general supportive therapy and specific therapy that includes measures to decrease the RBC volume or to increase the plasma volume. High-risk neonates (**Box 3**) should be routinely monitored for elevated hematocrit. This is especially applicable for small for date neonates, neonates who have suffered perinatal asphyxia and infants of diabetic mothers. In these high-risk neonates, hematocrit should be monitored at 2, 6, and 12 hours of age and thereafter if clinically indicated. Associated conditions such as hypoglycemia, respiratory distress, seizures, and circulatory compromise should be managed with specific therapies such as glucose infusion, respiratory support, anti-epileptics and vasoactive agents. Routine fluid supplementation based on the assumption of dehydration is not recommended. However, if clinical signs indicate dehydration and associated hemoconcentration, appropriate fluid relaxation and treatment of dehydration is mandated.

Partial exchange transfusion (PET) helps in reducing the hematocrit and relieves the symptoms. However, it should not be done routinely as it is not beneficial in improvement of long-term

neurological outcome. Colloidal and crystalloids appear to have equal efficacy in PET. The current indications of PET are:

- a. Any symptomatic neonate with a venous hematocrit of  $\geq 65\%$  where the symptoms are strongly attributable to polycythemia.
- b. Venous hematocrit  $\geq 75\%$  irrespective of the presence or absence of symptoms.

To determine the volume to be exchanged the following formula can be used:

$$\text{Volume (in mL)} = [(\text{Observed Hct} - \text{Desired Hct}) / (\text{Observed Hct})] \times \text{Blood volume (in mL/kg)}$$

Where the desired Hct is usually assumed as 50–55% and the blood volume is assumed as:

For  $< 1$  kg:  $100 \text{ mL} \times \text{body weight}$ ;  $1\text{--}2$  kg:  $90 \text{ mL} \times \text{body weight}$ ;  
For  $> 2$  kg:  $80 \text{ mL} \times \text{body weight}$

### IN A NUTSHELL

1. Anemia in the newborn is primarily due to blood loss and hemolysis.
2. Phlebotomy losses are an important cause of anemia in a sick newborn.
3. Blood transfusions should be used sparingly since they are associated with risks; in asymptomatic newborns blood transfusion should be considered only when hematocrit are less than 20%.
4. Chronic intrauterine hypoxia (as in late onset fetal growth restriction) is an important cause of polycythemia in newborns.
5. Partial exchange transfusion in newborns with polycythemia should be considered only in symptomatic neonates (symptoms attributable to polycythemia).

## Chapter 14.7

# The Bleeding Neonate

Arun Kumar

Pediatricians are faced from time to time with potentially life-threatening bleeding in infants. A systematic approach with appropriate laboratory support should lead to a successful outcome in the majority of infants. This chapter will provide readers with an overview of this topic from a clinician's viewpoint. The focus would be on the neonate presumed to have abnormal hemostasis. It will not delve into details of site specific bleeding such as intracranial or pulmonary hemorrhage. Thrombosis in the newborn is also considered beyond its scope. While the broad principles of treatment are discussed, these would ultimately be governed by local policies and resources.

## EPIDEMIOLOGY

There is paucity of information on the prevalence of bleeding episodes in neonates. In a prospective study on prevalence in a multicentric study in the UK, Australia and the USA, bleeding occurred in 25% of infants and was most common in preterm infants. Eleven percent infants had major or severe bleeds, 1% moderate and 13% minor bleeds. Of the 11 babies within the major bleeding group, two infants developed rectal hemorrhage, two had pulmonary hemorrhages and seven had intracranial hemorrhage. In the severe group of five infants, three had pulmonary hemorrhage and two had subaponeurotic bleeds with intracranial hemorrhages. One percent infants developed moderate bleeds (both had intraventricular hemorrhage without ventricular dilatation). Thirteen percent infants developed minor episodes with bleeding from the nasogastric tube being the most common source. Intracranial hemorrhage was also a commonly observed form of bleeding and 17% infants developing this in some form.

In developing countries, severe sepsis and hypoxic injury are not uncommon, and are often accompanied by bleeding from associated disseminated intravascular coagulation (DIC) and liver dysfunction. Also, prophylactic vitamin K may not be used consistently and hemorrhagic disease of the newborn remains an important cause. The prevalence of conditions associated with thrombocytopenia does not vary significantly across the globe. Coagulation disorders are relatively uncommon but more prevalent in communities with high prevalence of consanguinity.

## PHYSIOLOGY OF COAGULATION

The concentration of vitamin K-dependent coagulation factors (II, VII, IX, X) and contact factors (XI, XII, prekallikrein and high molecular weight kininogen) is low in neonates and gradually increases with age and gestation. The activated partial thromboplastin time is prolonged in neonates due to decreased plasma concentrations of the contact factors. Prothrombin time (PT) is also prolonged reflecting decreased plasma levels of vitamin K-dependent factors. The level of factors V, VIII and XIII are normal. Plasma concentrations of fibrinogen may be raised but thrombin C time is prolonged, due to the presence of *fetal* fibrinogen which has different properties to normal fibrinogen. Platelet counts are similar to adult ranges. Bleeding time is shorter in healthy neonates probably because of high hematocrit and increased concentrations and enhanced function of von Willebrand factor (vWF) and higher levels of vWF large multimers. The capacity of newborns to generate thrombin, dependent upon plasma concentrations of procoagulants, is reduced. Thus, the theoretically increased risk

of bleeding from decreased coagulation factors is balanced by the protective effects of physiologic deficiencies of the inhibitors of coagulation, as well as by the decreased capacity of the fibrinolytic system in infants. This implies that an abnormal result on tests of coagulation may not necessarily require treatment and needs interpretation in the clinical context.

## ETIOLOGY

Most bleeding in neonates is secondary to other disease processes. In a minority, the problem emanates from congenital defects in hemostasis. The causes could broadly be classified into the following categories:

- Thrombocytopenia, or rarely, disorders of platelet function
- Vitamin K deficiency
- Disseminated intravascular coagulation
- Liver cell failure
- Coagulopathies
- Iatrogenic
- Perinatal hemorrhage
- Congenital anomalies including vascular malformations.

Thrombocytopenia and vitamin K deficiency are discussed separately in this textbook. A brief discussion of some of the other causes as follows:

## Disseminated Intravascular Coagulation

This is commonly encountered with severe sepsis, hypoxia, hypotension, acidosis or hypothermia. There is activation of the coagulation cascade with consumption of platelets and coagulation factors, and secondary activation of fibrinolysis. The clinical presentation typically is bleeding from multiple sites including heel pricks and sites of insertion of intravenous lines. Laboratory tests will reveal a low platelet count, prolonged prothrombin and partial thromboplastin times, and decreased fibrinogen levels, with schizocytes in a peripheral blood smear. D-dimers are elevated but not diagnostic as these can be elevated in healthy neonates with no evidence of coagulopathy.

## Treatment

It comprises elimination of the trigger factor, with replacement of factors using fresh frozen plasma (FFP) and platelet concentrate as required. Packed cells may be indicated if the infant is anemic. A recommended approach is to maintain the platelet count more than  $50 \times 10^9/L$  ( $100 \times 10^9/L$  if ventilated, with recent surgical sites or actively bleeding), PT less than and equal to 3 seconds above the upper limit of normal and the fibrinogen more than 1 g/L. Although inhibiting the activation of the coagulation system with prophylactic dosing of heparin (5–10 U/kg/hour) has been considered, trials of anticoagulation in neonates have not been conclusive and the risk of bleeding may be increased. There is little experience with using antithrombin III in neonates.

## Liver Cell Failure

This is seen in neonates secondary to infection, including bacterial sepsis, neonatal herpes simplex virus (HSV) infection, other viral infections, primary liver disease or hypoxic injury, or inborn errors of metabolism. Neonatal HSV infection is an emerging important cause and this diagnosis should always be considered in any unwell infant presenting with a prolonged PT, jaundice and raised liver enzymes that may also be encephalopathic. Treatment consists of addressing the cause and correction of the coagulopathy, if there is bleeding, with vitamin K, FFP or cryoprecipitate. If a diagnosis of HSV is considered, intravenous acyclovir 20 mg/kg/dose 8 hourly should be commenced immediately pending the results of HSV polymerase chain reaction on blood and cerebrospinal fluid samples.

## Coagulation Disorders

These are relatively uncommon but can cause significant hemorrhage. Hemophilia A and B are the most frequently encountered conditions. Other disorders such as afibrinogenemia and deficiencies of other factors are rare but need to be considered in the differential diagnosis. von Willebrand disease only unusually presents in the neonatal period because of their higher vWF factor levels.

### Hemophilia

Hemophilia A and B are X-linked disorders characterized by deficiency of coagulation factors VIII and IX, respectively. Hemophilia A occurs in 1 in 5,000 live male births, and is about four times as common as hemophilia B. As awareness has increased and prenatal diagnosis has become available, diagnosis during the neonatal period has increased significantly. The sites of neonatal bleeding included circumcision site (45.49%), intracranial bleeding (17.69%), heel pricks (14.8%) and venipuncture sites (3.61%).

Where a family history is available, strategies available for management in pregnancy include preimplantation diagnosis, and offering fetal sexing to couples who wish to consider this option, either by chorionic villus sampling or ultrasound. There is also the option for third-trimester amniocentesis, as this may allow the diagnosis of an unaffected pregnancy. There is controversy regarding the merits of normal delivery versus an elective cesarean section. UK guidelines recommend that this should be informed by both obstetric and hemostatic factors, including maternal morbidity with cesarean section for hemophilia B carriers. Data from the Universal Data Collection Cohort suggests that when infants were grouped by presence or absence of family history, intracranial hemorrhage occurred more in vaginal births than cesarean births.

Invasive monitoring with scalp electrodes and fetal scalp blood sampling should be avoided as should application of obstetric forceps and ventouse extraction. On delivery, a sample of cord blood collected carefully without contamination from maternal blood, or a peripheral venous blood sample should be processed as soon as possible for coagulation screen and coagulation factor assay. The diagnosis of severe and moderate hemophilia can also be confirmed in the neonatal period. However, confirmation of mildly affected cases could be problematic due to overlap with the normal range necessitating repeat testing at around 6 months of age. These infants should not have any arterial stabs, and heel pricks should be kept at a minimum. Intramuscular injections should be avoided and vitamin K can be given orally. Circumcision if requested should be performed only with adequate preparation.

*Acute management of the bleeding* Infant requires recombinant factor VIII or IX as applicable to be administered as soon as possible. There is little information on the pharmacokinetics of replacement therapy in neonates and treatment is based on guidelines for older children. Guidelines published by the World Federation of Hemophilia on the Internet constitute an excellent resource and also include advice on duration of therapy where there are resource constraints.

If recombinant factor concentrate is not available, highly purified virally inactivated plasma derived factor VIII or IX products can be administered. Cryoprecipitate should only be used if factor concentrates are not available. If the diagnosis is not known, FFP, 15–25 mL/kg can be administered. The administration of desmopressin [1-deamino-8-D-arginine vasopressin (DDAVP)] may result in dilutional hyponatremia with consequent seizures, and should not be used for the treatment of neonates with mild hemophilia A. Those with suspected intracranial bleeding on ultrasound scan will usually need a CT or MRI scan of the head to establish the diagnosis.

Following confirmation of diagnosis, short-term prophylactic replacement therapy should be given in neonates at increased

risk of bleeding, e.g., following traumatic delivery, instrumental delivery, or a prolonged second stage of labor, and considered following preterm delivery. Children and neonates with severe hemophilia who have had a spontaneous central nervous system bleed should continue long-term prophylaxis.

### Other Coagulation Disorders

Congenital deficiencies of fibrinogen, prothrombin, factors V, VII, XI and XIII are very rare but can be encountered in communities with high prevalence of consanguinity. These can present with cord bleeding (especially fibrinogen and factor XIII deficiency) or intracranial hemorrhage. Treatment is with the appropriate concentrate where available including fibrinogen, recombinant factor VIIa, and factor XIII. Cryoprecipitate or FFP are alternatives. For factor II and X deficiencies, there are no specific concentrates available and prothrombin complex concentrates are the treatment of choice. Factor V deficiency can be isolated or coexist with factor VIII deficiency. Treatment is with FFP and factor VIII concentrates if applicable. Alternatives to these products are cryoprecipitate or FFP. Alpha 2-antiplasmin deficiency is treated with tranexamic acid or epsilon aminocaproic acid (EACA) but there is no neonatal data available for its use.

### Iatrogenic Bleeding

Disastrous bleeding can occur in neonates from dislodged arterial and umbilical lines. Recombinant tissue plasminogen activator used for thrombolysis in neonates has an associated risk of mild to severe bleeding. There is a significant risk of hemorrhagic complications after extracorporeal membrane oxygenation and cardiopulmonary bypass in neonates undergoing corrective heart surgery. These are secondary to anticoagulation, activation of the coagulation and fibrinolytic systems with consumption of coagulation factors, together with dilutional thrombocytopenia. Management includes careful monitoring of heparinization, replacement therapy with hemostatic factors and platelets, and use of drugs such as EACA and recombinant factor VIIa. A detailed discussion on this complex subject is beyond the scope of this chapter.

### Hemorrhage in the Perinatal Period

Massive fetal bleeding may result following placenta previa, placental abruption or incision of the placenta at cesarean section. Another potential problem is vasa previa. Accidental hemorrhage can occur following slippage of a cord clamp. Rupture of the umbilical cord and hematomas into the cord can occasionally lead to severe neonatal anemia with a high perinatal mortality rate. Fetomaternal hemorrhage can occur spontaneously and may be increased by invasive procedures such as fetal blood sampling and cesarean section.

## CLINICAL FEATURES

In addition to bleeding, the affected neonate may have other features indicating the etiology including the following:

- Petechiae, suggestive of low platelets.
- Ecchymosis, indicating a coagulopathy.
- Bleeding from umbilicus, circumcision site, large subgaleal bleeding, all indicating a possible coagulopathy.
- Oral mucous membrane bleeding, or an ooze rather than active bleeding from any site, suggestive of thrombocytopenia. Intracranial hemorrhage is usually associated with prematurity, traumatic delivery, arteriovenous malformations, and secondary to coagulopathies or thrombocytopenia.
- Jaundice, due to liver dysfunction.
- Signs of sepsis, including poor capillary refill and sclerema, full anterior fontanel.

- Blisters over presenting part, site of insertion of scalp electrodes or elsewhere, and seizures in HSV infection.
- Hepatosplenomegaly, in congenital infection.

A relatively well infant with bleeding could have immune thrombocytopenia, vitamin K deficiency, an inherited coagulation factor deficiency, or bleeding from anatomic lesions such as hemangioma. A sick infant with bleeding may have DIC, sepsis or liver failure.

## DIFFERENTIAL DIAGNOSIS

Some entities can masquerade as neonatal bleeding. Pinkish-orange urate crystals deposited from urine into the nappies of normal babies could be misinterpreted as bleeding. Sometimes, the newborn will swallow large quantities of maternal blood especially in the setting of antepartum hemorrhage and then either vomit dark brown maternal blood or pass large quantities of tarry stools. These infants would be clinically very well and laboratory tests would all come back as normal. An Apt test could help differentiate fetal from maternal blood but it is not reliable and persistent bleeding would merit investigation.

## APPROACH TO DIAGNOSIS

In the history, particular attention must be paid to birth details, risk factors for sepsis, use of instruments to augment labor, maternal drugs or illnesses during pregnancy, history of genital herpes, family history of coagulation disorders, and any previously affected siblings. A history of consanguinity would increase the risk of autosomal recessive conditions. Where there is prior information available indicating the possibility of a bleeding disorder in the neonate, meticulous planning of the care in labor and postnatal periods is essential. Physical examination covering the points as mentioned previously would assist in arriving at a possible diagnosis.

## Investigations

If there is clinically significant bleeding, the following tests would need to be performed as soon as possible: full blood count, peripheral blood smear, coagulation screening, PT, partial thromboplastin time, fibrinogen, thrombin clotting time, and blood for group and crossmatching.

Ideally, the sample for coagulation should be taken from a free flowing vein and it is important to ensure that the right volume of blood is collected to maintain the correct ratio with the anticoagulant in the sample bottle. Sometimes, the sample may be taken from an arterial line particularly in the neonatal intensive care unit setting. This is acceptable as long as sufficient blood has been drawn into a syringe beforehand to minimize heparin contamination, and the laboratory is informed about this, as they may be able to perform a reptilase time to help interpretation in the event of heparin contamination.

If a lumbar puncture is contemplated due to concerns with sepsis, this should not be performed until a coagulopathy has been excluded or corrected, and platelet count is above  $100 \times 10^9/L$ . A bedside ultrasound scan of the head helps to check for intracranial hemorrhage. This test is not reliable and if there is strong clinical suspicion, a CT or MRI scan may be required. A blood gas analyzer may be able to measure hemoglobin to help diagnose anemia rapidly. Similarly, if laboratory samples cannot be processed swiftly, a laboratory centrifuge if available would help with quick estimation of packed cell volume.

## Interpretation of Coagulation Tests

The normal values for full blood count and coagulation screen are different in newborn babies and also vary with age and gestation. **Table 1** gives accepted values for these parameters from widely

quoted sources in the literature. **Table 2** is a general guide to interpreting the results.

A number of studies have confirmed that age-related reference ranges for coagulation assays in the healthy population are analyzer and reagent dependent, yet many laboratories compare their pediatric results to either their adult reference range or to published pediatric reference ranges. Neither of these options is satisfactory. Be especially wary of overinterpreting borderline abnormal results and always discuss with an expert hematologist first.

If no abnormality is found in these tests and the infant is bleeding, rarer causes may need to be considered such as factor XIII deficiency,  $\alpha_2$ -antiplasmin deficiency or a platelet function disorder.

## MANAGEMENT

Sometimes, bleeding is mild and the laboratory parameters are stable. A typical example is amounts of hemorrhagic gastric aspirates from the nasogastric tube after perinatal stress, which can be managed expectantly or with a short course of H<sub>2</sub>-receptor antagonists. If bleeding is significant, time is of the essence for clinical intervention and is essential to maintain active liaison with the laboratory and hematology services.

While a member of the team collects information from the parents to help establish the diagnosis, other members should concentrate on examining the infant, ensuring that there is no life-threatening situation that requires immediate assistance. In the context of bleeding, checking for hemodynamic stability is of paramount importance.

Rapid intravenous access must be obtained, using an umbilical venous catheter if peripheral cannulation proves difficult. If the infant is actively bleeding and in shock, an intraosseous needle could be used to obtain access. After the relevant blood samples are collected, an initial bolus of 0.9% saline 10 mL/kg body weight may be needed if there are concerns about a slow capillary refill time. If the infant is pale and shocked at birth and born in a setting of possible severe bleeding, such as placenta previa, immediate transfusion of O-negative blood, 10–20 mL/kg as a slow intravenous push may be given without cross matching. Emergency *flying squad* blood units are usually kept in many delivery suites for obstetric hemorrhage and could be used for the newborn. You would need to follow local blood banking policies in this regard. In a less urgent situation, start treatment for possible associated illnesses such as sepsis while awaiting results of blood tests and administer further treatment based on the results. Initiate supportive treatment as indicated by the infant's condition. Once results of initial tests become available, appropriate therapy for the bleeding diathesis can be given.

1. *Vitamin K<sub>1</sub>*, 1 mg intravenously for vitamin K deficiency. Intramuscular injections should be avoided in any bleeding diathesis.
2. *Packed cell transfusion*, 10–20 mL/kg bodyweight given over 4 hours for significant hemorrhage. If profuse, proportionately larger volumes may be required more quickly. Blood for transfusion needs to be crossmatched with mothers' serum. In addition to routine screening for hepatitis B, syphilis and HIV, blood for neonatal transfusions should be obtained from cytomegalovirus negative donors and should also be leukodepleted. Blood from related donors especially parents should be avoided as it could pose potential immunological risks and a greater likelihood of graft versus host disease. Irradiated blood is indicated when the infants have received intrauterine transfusions or are known to be immunocompromised.
3. *Fresh frozen plasma* obtained from screened donors, is used where rapid correction of coagulation defects is desired as in bleeding associated with vitamin K deficiency, DIC and in coagulation deficiencies where factor concentrate is not available. One infusion of 12–15 mL/kg infused at the rate

of 10–20 mL/kg/hour with careful monitoring for acute transfusion reactions or circulatory overload.

4. *Platelet concentrates* are indicated in clinically significant thrombocytopenia which is discussed in a separate chapter. A platelet concentrate obtained from one donor is suspended in 50–75 mL of plasma. The dose is 10–20 mL/kg, which would be expected to increase the platelet count by  $100 \times 10^9/L$ . In sick neonates, however, such increases in platelet numbers are seldom seen due to rapid consumption or sequestration. It should be given as soon as possible usually at a rate of 10–20 mL/kg/hour.
5. *Factor VIII or IX concentrates* are indicated in hemophilia. Details regarding dosage of these concentrates appear in a reference provided elsewhere in the text.
6. *Cryoprecipitate* is used as a more concentrated source of fibrinogen than FFP and is primarily indicated when the fibrinogen level is less than 0.8–1.0 g/L in the presence of bleeding from acquired or congenital hypofibrinogenemia. The dose is 5–10 mL/kg of body weight.
7. *Exchange transfusion* can be performed in DIC especially if associated with sepsis.
8. *Whole blood* is used principally for exchange transfusions and possibly for resuscitation in hypovolemic states.
9. *Recombinant activated factor VII (rFVIIa)* is a novel therapeutic alternative for bleeding associated with coagulation factor deficiencies. Use in neonates is based solely on case reports, case series, and prospective uncontrolled studies. In most cases, treatment was effective in controlling hemorrhage. Doses of 40–300 µg/kg were used, but further investigation of neonatal rFVIIa pharmacokinetics is required to determine an optimal dose. The

safety of rFVIIa in neonates remains a concern as thrombotic complications have been observed. In the majority of these reports, rFVIIa was used as a desperate final measure, after standard measures had failed to control life-threatening hemorrhage.

The laboratory tests may need to be repeated 8–12 hourly until stable. If bleeding is severe in areas such as the gut, or in the brain, urgent consultation with a pediatric surgeon or neurosurgeon would be needed to plan management. Bleeding in the setting of severe liver failure may need the input of a pediatric hepatology team. Bleeding from the lung (pulmonary hemorrhage) requires intubation and ventilation, or manipulation of ventilator settings to control pulmonary edema in addition to treatment of coagulopathy. A dose of surfactant may help to improve pulmonary function.

The use of all blood products requires to be balanced with potential risks. If large amounts of blood are transfused, this by itself can carry the risk of further hemostatic and metabolic complications which require to be anticipated and managed.

## OUTCOME AND COMPLICATIONS

Most episodes of bleeding can be managed effectively. Sometimes, bleeding may be torrential and unresponsive to treatment as with a congenital vascular malformation. Intracranial hemorrhage carries a guarded prognosis with risk of long-term neurological handicap. Neonatal HSV infection with liver failure also carries a poor prognosis. The outcome for conditions such as alloimmune thrombocytopenia is excellent but those with congenital coagulopathies require a lifetime of follow-up and treatment.

\*Data from Andrew M, et al. All infants received vitamin K at birth

## PREVENTION

Universal administration of vitamin K in newborn infants would be a cost-effective strategy for prevention of severe bleeding. Wherever possible, careful planning prior to delivery of high-risk infants would invariably improve the outcome. Genetic counseling should be arranged for couples of infants affected with inheritable coagulation disorders. Preimplantation genetic diagnosis is available for hemophilia and prenatal diagnosis is possible for several congenital coagulopathies allowing parents the option for termination or proceeding toward early intervention and therapy.

### IN A NUTSHELL

1. Neonatal bleeding is usually secondary to other medical conditions, but could be due to a primary problem with hemostasis.
2. Laboratory ranges for neonatal coagulation parameters differ from other age groups.
3. Liaison with hematology is vital to ensure correct interpretation of test results, and appropriate management, especially the use of blood products.
4. Wherever possible, an antenatal plan for management of the high-risk infant would ensure smooth delivery of care.

## Chapter 14.8

# Hemorrhagic Disease of the Newborn

JN Sharma

The term hemorrhagic disease of newborn (HDN) was first coined in 1894 by Townsend, who first described the picture of bleeding from multiple sites in otherwise healthy infants in the absence of trauma, asphyxia, or infection on days 1–5 of life. The link between vitamin K and spontaneous hemorrhage was first reported in 1929. Recognition of the association between vitamin K deficiency and hemorrhagic disease of newborn quickly followed, with subsequent treatment of HDN with vitamin K. The original term hemorrhagic disease of newborn was replaced with the term vitamin K deficiency bleeding (VKDB) in 1999, because the former entity included conditions with bleeding due to other causes.

### PATHOPHYSIOLOGY

None of the coagulation factors cross the placenta from the mother to the fetus. At birth, the concentration of vitamin K dependent factors (Factors II, V, VII, IX and X) and contact factors (factor XI and factor XII) are reduced to about 50% of normal adult values and are further lower in preterm infants.

Vitamin K is required for gamma carboxylation of glutamic acid residues of the protein precursors of the factors II, VII, IX and X which are synthesized in the liver. These protein precursors are termed as PIVKA (proteins induced in vitamin K absence). It is only after gamma carboxylation that these proteins acquire the ability to chelate calcium and to be subsequently activated during coagulation. This action of vitamin K is limited in preterm. Moreover, precursor proteins themselves are deficient in newborn, often below 30% of adult value, as the immature liver is not capable of optimal synthesis of many precursor proteins.

Vitamin K facilitates post-transcriptional carboxylation of factors II, VII, IX and X. In the absence of carboxylation, such factors form PIVKA. It is a sensitive marker of vitamin K status.

A moderate degree of decrease in factors II, VII, IX and X normally occurs in all newborn infants by 48–72 hours after birth. The levels gradually return to normal birth levels by 7–10 days of age. This transient deficiency of vitamin K is due to lack of transplacental transfer of free vitamin K and absence of normal intestinal bacterial flora in the first few days of life which is responsible for the synthesis of vitamin K. There occurs an accentuation and prolongation of this deficiency between the second and seventh days of life resulting in spontaneous and prolonged bleeding. This is frequently seen in preterm and rarely in term infants. Breastmilk is a poor source of vitamin K and hemorrhagic complications are more frequent in exclusively breastfed babies.

### ETIOLOGY

Vitamin K deficiency bleeding is a bleeding disorder which results from the deficiency of vitamin K-dependent coagulation factors viz. factor V, factor VII, factor IX and factor X. Vitamin K is essential for alpha-carboxylation of these factors which converts them to active forms. The newborn has relative vitamin K deficiency for the following reasons:

- Low vitamin K stores at birth
- Poor placental transfer of vitamin K
- Low levels of vitamin K in breastmilk
- Sterility of gut

The intake of vitamin K in exclusively breastfed babies is less than 5 microgram/L in comparison to formula fed infants whose intake is 50 mg/L. Hence VKDB is exceedingly rare in formula fed infants. On rare occasions, deficiency of vitamin K dependent coagulation factors is due to a genetic defect of vitamin K metabolism. Affected infants may present with bleeding in the intrauterine or early neonatal period.

### CLINICAL MANIFESTATION

#### Early HDN

Early HDN occurs as a result of in utero severe vitamin K deficiency precipitated by maternal intake of drugs like phenytoin, and phenobarbitone. These drugs given during pregnancy interfere with vitamin K metabolism and may cause severe deficiency of vitamin K dependent coagulation factors viz. factors II, VII, IX and X in the fetus. In early HDN, onset of bleeding may occur in utero or within 24 hours of birth. Bleeding is usually severe and life-threatening in the form of concealed hemorrhage in the cranium, thorax and abdomen. Large ecchymosis, subcutaneous hemorrhage, external bleeding may also occur. The prothrombin time (PT) is prolonged. Bleeding is usually corrected by administration of vitamin K but response may be delayed or poor in some cases. Such a situation necessitates administration of fresh frozen plasma (FFP).

#### Classical HDN

This is the most common form. It is a result of severe deficiency of vitamin K. Vitamin K stores at birth is very small and rapidly depleted. Breastmilk contains small amount of vitamin K. The amount of milk during the first few days cannot supply adequate amount of vitamin K. In addition, colonization of gut which is necessary for endogenous synthesis of vitamin K is delayed. Hence, breastfed babies can develop bleeding due to severe transient deficiency of prothrombin, factors VII, IX and X. Onset of bleeding usually occurs between the second and fourth day of life, may occur from 1 day to 7 days. The bleeding may be in the form of umbilical stump hemorrhage, hematemesis and/or melena, ecchymosis, epistaxis, subgaleal hemorrhage, bleeding from puncture sites and intracranial hemorrhage. The PT and activated partial thromboplastin time (APTT) are very prolonged. The platelet count, thrombin time and fibrinogen level are normal. The factors II, VII, IX and X are significantly decreased. Administration of vitamin K results in cessation of bleeding, improvement of coagulation defect within a few hours.

#### Late HDN

In late HDN, the onset of bleeding is after the first week, may be between second and sixteenth weeks. Bleeding can occur from any site but more commonly from intracranial vessels, mucous membranes, skin and gastrointestinal tract (GIT). Intracranial bleed may be a devastating complication which is seen in about one-third of cases. Late HDN is often associated with vitamin K malabsorption as seen in biliary atresia and other hepatobiliary disorders.

### DIFFERENTIAL DIAGNOSIS

Other forms of bleeding may be clinically indistinguishable from hemorrhagic disease of newborn responsive to vitamin K. These forms are neither prevented nor successfully treated with vitamin K. It may be emphasized that any of the congenital defects in coagulation can result in a clinical pattern identical to hemorrhagic disease of newborn. The conditions include the following:

*Congenital defects in blood coagulation (viz. factor VIII and IX deficiency)* In 5–35% of cases of congenital deficiency of factor

VIII and IX may present with bleeding in the neonatal period in the form of umbilical cord bleeding, melena, and postcircumcision bleeding. These conditions do not respond to vitamin K but requires FFP or specific factor replacement.

**Disseminated intravascular coagulopathy (DIC)** Neonates affected with disseminated intravascular coagulopathy are usually preterm. It is a disorder that results in consumption of clotting factors, platelets and anticoagulant proteins resulting in widespread intravascular deposition of fibrin leading to tissue ischemia and necrosis, generalized hemorrhagic state and microangiopathic hemolytic anemia. DIC frequently accompanies a severe systemic disease. It may be triggered by a life-threatening process viz. hypoxia, acidosis, infection, tissue necrosis, shock and endothelial damage.

The clinical manifestations include bleeding from venipuncture sites and surgical incision. It is the common initial presentation. There may be petechiae, ecchymosis in skin. The effect of thrombosis and ischemia include large areas of infarction in skin and subcutaneous tissue, renal failure, hemolysis and anemia. There can be life-threatening bleeding viz. intra-cranial bleed which necessitates treatment with FFP and blood transfusions. The laboratory findings include low hemoglobin and severely decreased platelet count. The prune belly syndrome shows fragmented RBCs, burr cells, helmet shaped RBCs. The PT, APTT, thrombin time are prolonged. The fibrin degraded products are present in blood. The levels of protein C and S are low.

**Swallowed maternal blood syndrome** It is characterized by passage of blood or bloody stool usually on the second or third day of life. It may be confused with gastrointestinal bleed. The blood may be swallowed by the infant during delivery or from a fissure in the mother's nipple. Differentiation from gastrointestinal hemorrhage can be done by Apt test.

**Apt test** A blood stained diaper or some grossly bloody stool is rinsed with a suitable amount of water to obtain a distinctly pink supernatant hemoglobin solution. The mixture is centrifuged and the supernatant fluid is decanted. To 5 parts of this fluid one part of 1% sodium hydroxide is added. Within 1–2 min a color reaction takes place. A yellow brown color indicates maternal blood. A persistent pink color indicates presence of fetal hemoglobin and it is infant's blood.

**Subcutaneous ecchymosis in preterm neonate** Widespread subcutaneous ecchymosis in preterm infants at or immediately after birth is apparently a result of fragile superficial blood vessels. Occasionally an infant is born with petechiae limited to face, head and neck. It is probably as a result of venous obstruction by nuchal cord or sudden increase in intrathoracic pressure during delivery.

## LABORATORY DIAGNOSIS

A prolonged PT with international normalized ratio greater than 3.5 in presence of normal fibrinogen level and platelet count is highly suggestive of vitamin K deficiency. Infants with liver disease usually also have vitamin K independent coagulation factors. With DIC there is deficiency of coagulation factors, a low platelet count and elevated levels of fibrin degradation products. Hereditary coagulation factor deficiency can be excluded by single factor analysis.

## MANAGEMENT

The management includes supportive treatment with blood component therapy and administration of vitamin K in appropriate doses as indicated. An infant with hemorrhagic disease of newborn

may present with or without shock depending on the severity of bleeding.

## Infant in Shock

If there is significant hemorrhage and the infant is in shock, it will present with cold peripheries, tachycardia, capillary refill time more than 3 sec and a blood pressure less than 35 mm Hg. However, it should be noted that the hemoglobin level may not fall for 2–3 hours. Further, the blood pressure also may not fall initially until potentially life-threatening blood loss has occurred.

An infant in shock requires a rapid transfusion of 15–20 mL/kg of uncross matched O-negative blood or 10–20 mL/kg of normal saline over 5–15 min. If there are no signs of recovery from shock another bolus should be given over 15–20 min. The blood pressure and central venous pressure (CVP) should be monitored. The aim is to achieve blood pressure more than 40 mm Hg (in term infants) and CVP less than 8 cm H<sub>2</sub>O. If necessary a further transfusion should be given cross matched against maternal blood, 10–30 mL/kg over 2–3 hour accompanied by 1–2 mg/kg furosemide IV.

## Infant not in Shock

If the infant is not in shock, and not given vitamin K at birth, it should be given immediately as follows:

- (i) In classical HDN, 1–2 mg IV
- (ii) In early HDN, 2 mg IV
- (iii) In late HDN, 1 mg IV and then every week.

The infant may need a transfusion with packed red cells 10 mL/kg over 2–3 hours with 2 mg/kg furosemide IV, to raise hemoglobin to 10–12 g/dL. It needs mention that 10 mL/kg of packed red cells will raise hemoglobin by 2–3 g/dL or the hematocrit by 10%.

All critically ill infants with weight less than 1,500 g should be given IV FFP, 10 mL/kg if PT and partial thromboplastin time (PTT) are prolonged.

In classical HDN, after administration of vitamin K, a rise in coagulation factor levels and function occurs within 2 hours of therapy. Complete correction occurs within 24 hours. Vitamin K should not be given IM because large hematomas may form at the site of injection. Intravenous vitamin K should be given slowly because it may induce anaphylactic reaction. In infants with moderate to severe bleeding, FFP 10–15 mL/kg should be administered in addition to vitamin K. In severe bleeding, 2–3 doses of vitamin K may be required.

In infants with early HDN, if the mother is treated with phenytoin, phenobarbitone, INH, salicylates, delivery should be by cesarean section to avoid trauma. The baby should be given vitamin K at postpartum and the dose repeated after 24 hours. FFP administration may be required if fresh bleeding occurs. The platelet, PT, PTT should be monitored. In Late HDN, the underlying condition should be treated. Weekly vitamin K should be given for the first 3 months after birth or till the underlying disorder is controlled.

## PREVENTION

Hemorrhagic disease of newborn due to vitamin K deficiency can be prevented by administration of vitamin K, 1 mg IM, to newborn babies immediately after birth. It is safe and is not associated with an increased risk of childhood cancer. However, it is not uniformly effective in prophylaxis in the preterm. In the preterm, IV dose of 0.2–0.4 mg/kg has been advocated. A recent study showed that intravenous administration of 0.2–0.4 mg/kg vitamin K results in vitamin K plasma levels comparable to after IM injection in the term. Effectiveness of oral vitamin K has not been established; hence not recommended for routine use. Pregnant women

receiving oral anticonvulsant therapy should be given about 10–20 mg/day of vitamin K orally for 15–30 days before delivery to prevent overt vitamin K deficiency in their infants after birth.

### IN A NUTSHELL

1. Hemorrhagic disease of the newborn (HDN) is due to vitamin K deficiency.
2. HDN has three presentations, early (within 24 hours); classical (1–14 days) and late (after 2 weeks). Classical is the most common form.
3. Detection of PIVKA (proteins induced in vitamin K absence) in blood is most confirmatory of HDN.
4. Intracranial hemorrhage can be a devastating complication of HDN.
5. Vitamin K at birth can prevent HDN and should be given to all newborns at birth.

## Chapter 14.9

Thrombocytopenia  
in the Newborn

Pradeep Sharma

Nearly 1% of term neonates and 20–35% of preterm neonates have platelet counts less than 150,000/ $\mu$ L. Recent data suggests a lower normal limit of 120,000/ $\mu$ L for preterm neonates during the first few days of life. In a series of more than 11,000 neonatal intensive care unit patients with severe thrombocytopenia (platelet count less than 50,000/ $\mu$ L at two or more occasions) occurred in 2.4% of overall admitted neonates and 14% in extremely low birth weight neonates.

## ETIOLOGY

The primary causal factors soon after birth are intrauterine growth restriction, maternal hypertension whereas later on sepsis and necrotizing enterocolitis are responsible for thrombocytopenia. Other factors are maternal immune thrombocytopenia (ITP) and neonatal alloimmune thrombocytopenia (NAIT, **Table 1**).

**Table 1** Classification of neonatal thrombocytopenia

Early onset (<72 hours)	Placental insufficiency
	Perinatal asphyxia
	Congenital and perinatal infections
	Alloimmune thrombocytopenia
	Autoimmune thrombocytopenia
Late onset (>72 hours)	Thrombosis
	Late onset sepsis
	Necrotizing enterocolitis
	Catheter related thrombosis

## PATHOPHYSIOLOGY

Thrombocytopenia in the first few days after birth is often due to placental insufficiency, perinatal hypoxia and antenatal/perinatal infection with reduced megakaryopoiesis. After 72 hours of birth, severe thrombocytopenia in sick preterm newborns is often due to sepsis or necrotizing enterocolitis. There is cytokine release with suppression of platelet production and increased consumption.

Maternally derived antibodies can cause early thrombocytopenia by immune destruction of platelets. These antibodies may also cause platelet dysfunction leading to increased bleeding tendency. NAIT should be suspected when an otherwise healthy newborn presents with severe thrombocytopenia within 48 hours of birth. Serological testing can confirm maternal antihuman platelet antigen-1a (anti-HPA-1a) or anti-HPA-5b platelet antibodies.

Maternal ITP is another cause of neonatal thrombocytopenia suspected in otherwise healthy newborn. The platelet antibodies cross the placenta to the fetal circulation. The maternal platelet count should be checked if thrombocytopenia is unexpected in a newborn. The platelet count will increase within a week but sometimes may take up to 2 months. Intracranial hemorrhage is less commonly seen than in NAIT.

## CLINICAL MANIFESTATIONS

The main clinical concern for neonates with severe thrombocytopenia is major bleeding especially intraventricular and periventricular hemorrhage (IVH-PVH). In a prospective study across seven neonatal units, 169 neonates with platelet count less than 60,000/ $\mu$ L were enrolled. Major hemorrhage occurred in 13% of severely thrombocytopenic patients (IVH 53%, pulmonary 26%, renal 11%). The majority (84%) who had a major hemorrhage were born at less than 30 weeks gestation.

## Platelet Count and Bleeding

There is no relationship between the lowest platelet count and serious bleeding like pulmonary hemorrhage and intraventricular hemorrhage (IVH) although there is a higher incidence of cutaneous bleeds and gastrointestinal hemorrhage. There may be factors other than thrombocytopenia linked to the pathogenesis of these severe types of bleedings. Some studies have shown lower platelet counts in preterm neonates with IVH but it remains unclear whether thrombocytopenia caused IVH or occurred after IVH due to consumptive mechanisms. The close temporal relationship between thrombocytopenia and bleeding in sick neonates does not in itself establish cause and effect relationship nor does it provide justification for giving platelet transfusion to attempt correction of low platelet counts.

## EVALUATION

The evaluation should be started with examination of the placenta for multiple hemangiomas. Ask the mother for a history of previous bleeding that might suggest a diagnosis of maternal ITP, ingestion of drugs that might cause thrombocytopenia in the mother and the infant (e.g., quinidine, quinine); previous siblings affected with purpura, suggesting either immune or inherited thrombocytopenia and skin rash or exposure to rubella during pregnancy. Serologic evidence of congenital infections should be sought (e.g., syphilis, cytomegalovirus, herpes virus, toxoplasmosis). A normal maternal count differentiates alloimmunization from maternal ITP.

The newborn should be examined for hepatosplenomegaly and congenital anomalies suggestive of intrauterine infections. Jaundice with hepatosplenomegaly suggests infectious or hemolytic process. Deformity and shortening of the forearms suggest bilateral absence of the radii with associated amegakaryocytic thrombocytopenia. A single large hemangioma or multiple smaller hemangiomas point to possible platelet trapping and bruises should be searched for internal hemangiomas.

Complete blood count should include hemoglobin, leukocyte count, platelet count and blood smear. Anemia may be associated from blood loss, concurrent hemolysis or marrow infiltration by congenital leukemia. Mild leukocytosis may be there in infection or blood loss but if this exceeds 50,000/ $\mu$ L, it may point to congenital leukemia. In case of persistent thrombocytopenia with no cause identified, bone marrow examination should be considered.

## TREATMENT

## Platelet Transfusions

Two types of platelet products are available: pooled platelets derived from whole-blood donations and apheresis platelets collected by cell separation techniques. Splits of units of platelet concentrates may be prepared for neonatal use. After production, platelet concentrates are stored in plasma in incubators at 20–24°C for 5 days or more depending on use of bacterial screening methods. Platelets must be agitated during storage before transfusion. The recommended dose varies between 10 mL/kg and 20 mL/kg.

### Evidence of Efficacy

Platelet transfusion in a bleeding severely thrombocytopenic newborn has become a standard of care. The role of prophylactic platelet transfusions to keep the platelet count above a certain threshold in a nonbleeding patient is not supported by evidence. The guidelines and recommendations for neonatal platelet transfusion are based on consensus and show differences between countries and hospitals. The consensus based on expert opinions advise transfusing platelets in nonbleeding patients if platelet count is below 20,000/ $\mu$ L. This arbitrary figure is not based on any evidence and the clinician can use his own judgment depending upon the sickness of the patient and the trend in platelet counts. There is a large randomized trial running in the UK, the Netherlands and Ireland. The platelets for neonatal transfusion study 2 is underway comparing a threshold of 50,000/ $\mu$ L with 25,000/ $\mu$ L in neonates with gestational age less than 34 weeks. The primary outcome will be death or major bleed in the first 28 study days.

### Risks of Platelet Transfusions

Platelets are biological agents and are associated with risks. Data from the United Kingdom's Serious Hazards of Transfusion (SHOT) national hemovigilance scheme have shown a disproportionate number of overall adverse events in neonates compared with adult and pediatric population. Platelets are the blood component most likely to be contaminated by bacteria as they are stored at room temperature. It is highly likely that there is under-recognition of adverse events in infants who are already sick from other causes. There has been no relationship between lowest platelet count and mortality, however direct relationship has been observed between the number of transfusions and mortality although mortality cannot be directly ascribed to platelets. It is explained in part by the fact that sick patients need more platelet transfusions but partly by adverse effects of platelet transfusions.

### IN A NUTSHELL

1. Fetal growth restriction and maternal hypertension are common causes of early onset thrombocytopenia in the newborn, while sepsis is an important cause of late onset thrombocytopenia.
2. There is little evidence to support the degree of thrombocytopenia with major bleeds like pulmonary hemorrhage and intraventricular bleeds.
3. In nonbleeding neonates platelet transfusions should be considered only when platelet counts are less than 20,000/ $\text{mm}^3$ .

## Chapter 14.10

# Cyanosis in the Newborn

K Anil Kuruvilla, Vijay Gupta

Cyanosis is bluish discoloration of the tissues that results when the absolute level of deoxygenated hemoglobin in the capillary bed exceeds 3 g/dL. The appearance of cyanosis depends upon the absolute concentration of reduced hemoglobin rather than the ratio of deoxygenated to oxyhemoglobin. Before understanding the basic pathophysiology related to newborn cyanosis, one should understand oxygen transport and a few other terminologies:

## OXYGEN TRANSPORT

Oxygen is found in the body in three different states: (1) Oxygen in the airway of the respiratory tract; (2) Oxygen dissolved in the plasma; and (3) Oxygen bound to hemoglobin. The amount of oxygen which can be dissolved in plasma depends on the solubility coefficient of oxygen (i.e., 0.3 mL oxygen per 100 mL plasma per 100 mm Hg PaO<sub>2</sub>). Each 1 g of hemoglobin can combine to 1.34 mL of O<sub>2</sub> at 38°C. Each gram can bind to 1.39 mL oxygen under physiological conditions but not all hemoglobin is available for binding.

## Oxygen Carrying Capacity

The capacity of hemoglobin to carry the maximal amount of oxygen is 1.34 mL/g hemoglobin. Hence, the amount of oxygen in the arterial blood at any given point of time known as *oxygen content* can be calculated by the formula:

$$\text{CaO}_2 = (1.34 \times \text{Hb\%} \times \text{SaO}_2) + (0.003 \times \text{PaO}_2)$$

where CaO<sub>2</sub> = oxygen content, Hb% = hemoglobin concentration, SaO<sub>2</sub> = arterial oxygen saturation, PaO<sub>2</sub> = partial pressure of oxygen in arterial blood.

## Saturation (SaO<sub>2</sub>)

It is the proportion of hemoglobin in a blood sample that is saturated with oxygen at a given partial pressure. Pulse oximetry provides an excellent noninvasive and continuous assessment of oxygen saturation. This is different from PaO<sub>2</sub>, which is the partial pressure of oxygen in the artery.

At any given arterial oxygen saturation, blood having increased hemoglobin concentration will have higher oxygen content and can carry more oxygen as compared to blood having lower hemoglobin concentration. Hypoxia may be present in severe anemia caused by low oxygen content (low hemoglobin), although PaO<sub>2</sub> may be normal. Hypoxemia is caused by low PaO<sub>2</sub>, and its relationship to hypoxia is dependent on blood flow, hemoglobin concentration, and the affinity of hemoglobin to oxygen. Thus, an infant could be normoxemic but could still be hypoxic because of severe anemia, poor perfusion, or conditions in which hemoglobin is tightly bound to oxygen (increased affinity of hemoglobin to oxygen). As cyanosis is dependent upon the absolute concentration of reduced hemoglobin, hypoxemia may or may not correlate with the degree of cyanosis.

## ETIOPATHOGENESIS

The causes of cyanosis in newborn can be pulmonary, cardiovascular, neurologic, or hematologic in origin (**Table 1**). Cyanosis can be the result of one of the following pathologic mechanisms:

- Alveolar hypoventilation*: Neurologic illness, e.g., apnea of prematurity, neuromuscular disorders, central nervous system (CNS) dysfunction.
- Ventilation-perfusion mismatch*: Pneumonia, atelectasis

- Right to left shunt*:
  - Intracardiac (e.g., Tetralogy of Fallot)
  - Intrapulmonary (e.g., perfusion of nonventilated areas of the lung)
- Diffusion impairment*: Interference with alveolar-arterial diffusion (e.g., pulmonary edema)
- Abnormal hemoglobin*: With decreased oxygen affinity (e.g., methemoglobinemia).

## METHEMOGLOBINEMIA

Methemoglobin results from oxidation of hemoglobin molecules from the normal ferrous to ferric state. Normal methemoglobin levels are less than 1%, which is kept in check by the enzyme within the red blood cells (methemoglobin reductase). Newborn infants having increased fetal hemoglobin are more susceptible to methemoglobinemia due to easy oxidation of fetal hemoglobin to ferric state as compared to adult hemoglobin.

## Pathology

The altered heme molecule in ferric state is unable to bind to oxygen, with increased oxygen affinity of remaining normal hemoglobin molecule, resulting in decreased oxygen release to tissues. The risk factors for methemoglobinemia include increased oxygen stress; administration of topical anesthetics (prilocaine), antibiotics (sulfonamides), metoclopramide, nitrite or nitrates containing products (inhaled nitric oxide); cytochrome b5 reductase deficiency; and abnormal hemoglobin resistant to reduction (hemoglobin-M).

## Presentation

Newborn infant presents with slate-gray cyanotic appearance with no respiratory distress. Arterial blood appears chocolate brown on exposure to room air with normal PaO<sub>2</sub> levels. Pulse oximetry may show higher saturations rather than true levels of oxyhemoglobin. The severity of hypoxia is quite out of proportion to the degree of cyanosis.

## FACTORS DETERMINING DETECTION OF CYANOSIS

There are several factors that determine the clinical detection of cyanosis in the newborn. These include the hemoglobin concentration, conditions affecting the oxygen dissociation curve, fetal hemoglobin, and skin pigmentation.

## Hemoglobin Concentration

The detection of cyanosis is earlier in a polycythemic child as compared to an anemic child, as the appearance of the cyanosis depends on the absolute concentration of reduced hemoglobin ( $\geq 3\text{ g/dL}$ ) rather than relative concentrations of oxygenated or deoxygenated hemoglobin. As shown in **Figure 1**, patient A becomes cyanotic at 88% SaO<sub>2</sub> being polycythemic (Hb = 25%) as compared to patient E who appears cyanotic when saturation falls below 57% (being anemic Hb = 7 g/dL). Though all patients have the same amount of reduced hemoglobin (3 g/dL), the appearance of cyanosis differs in all patients (from A to E) depending upon the total hemoglobin concentrations.

## Oxyhemoglobin Dissociation Curve

Arterial oxygen saturation when plotted against the partial pressure of oxygen forms the oxyhemoglobin dissociation curve which is nonlinear or sigmoid shaped. The partial pressure of oxygen at which the hemoglobin is 50% saturated is called as P<sub>50</sub>. The oxygen dissociation curve shifts to the left with increase of fetal hemoglobin and decrease in H<sup>+</sup>, CO<sub>2</sub>, temperature and 2,3 DPG;

**Table 1** Causes for cyanosis in the newborn period

<b>Pulmonary lesions (Intrapulmonary right to left shunt)</b>	
Primary parenchymal diseases	Respiratory distress syndrome/hyaline membrane disease Transient tachypnea of newborn Aspiration syndromes (e.g., meconium, blood) Pneumonia Pulmonary hemorrhage Pulmonary edema
Anatomic airway obstruction	Choanal atresia Laryngeal web Pierre Robin syndrome Tracheal stenosis Absent pulmonary valve syndrome Pulmonary sling
Congenital defects	Tracheo-esophageal fistula (TEF) Congenital diaphragmatic hernia (CDH) Hypoplastic lung Cystic adenomatoid malformation Pulmonary sequestration
Extrinsic compression of lungs	Bronchogenic cyst Air leak syndrome (pneumothorax, pneumomediastinum) Chylothorax/Pleural effusion Thoracic dystrophies or dysplasias Pulmonary interstitial or lobar emphysema
Persistent pulmonary hypertension	
<b>Primary cardiac lesion*</b>	
Decreased pulmonary blood flow (Intracardiac right to left shunt)	Critical pulmonary stenosis, tricuspid atresia Pulmonary atresia/intact ventricular septum Tetralogy of Fallot Ebstein anomaly Total anomalous pulmonary venous connection with obstruction
Normal or increased pulmonary blood flow (Intracardiac mixing)	Hypoplastic left heart syndrome Transposition of great arteries Truncus arteriosus Tetralogy of Fallot/pulmonary atresia Complete atrioventricular canal Total anomalous pulmonary venous connection without obstruction Other single ventricle complexes
<b>Hypoventilation</b>	
	Central nervous system lesions Neuromuscular disease Hoffman disease Congenital myotonic dystrophy Sedation Sepsis Pulmonary arteriovenous malformation
<b>Hematological</b>	
	Polycythemia/ hyperviscosity syndromes Methemoglobinemia Sulfhemoglobinemia
<b>Neurological</b>	
	Central nervous system dysfunction Drug-induced depression of respiratory drive Postasphyxial cerebral dysfunction Intraventricular hemorrhage Subarachnoid hemorrhage Subdural hematoma Meningitis/encephalitis Seizures Hypoglycemia Phrenic nerve paralysis

\*Common cardiac causes of cyanosis in newborn can be remembered by 5Ts (Transposition of great artery (TGA), Tetralogy of Fallot (TOF), total anomalous pulmonary venous connection, truncus arteriosus and tricuspid atresia).

it shifts to the right with increase in  $H^+$ ,  $CO_2$ , temperature and 2,3 DPG and decrease in fetal hemoglobin. Hence, physiological factors which shift the oxygen dissociation curve to the left may produce significant fall in  $PaO_2$  for a given  $SaO_2$  as compared to factors which shift the curve to the right (**Fig. 2**).

### Conditions Affecting the Oxygen Dissociation Curve

The binding of oxygen to hemoglobin is dependent on various physiological factors. Factors that decrease oxygen affinity of hemoglobin include acidosis, increased temperature, increased level of 2,3 diphosphoglycerate (2,3 DPG) and hypercarbia. Factors that increase oxygen affinity of hemoglobin include alkalosis, decreased temperature, decreased level of 2,3 diphosphoglycerate (2,3 DPG), increased fetal hemoglobin and hypocarbia.

Newborn infants having higher levels of fetal hemoglobin as compared to their adult counterparts will shift the curve to left. Hence for a presumed  $SaO_2$  of 50%, if the  $PaO_2$  in adult is around 30 mm Hg, it will be almost 20 mm Hg in neonates (**Fig. 2**). Hence, newborn infants having higher fetal hemoglobin levels will be more hypoxemic as compared to infants or adult counterparts with decreased fetal hemoglobin levels. Hence, cyanosis will be detected at lower  $PaO_2$  in newborns who have more of fetal hemoglobin and less 2,3 DPG levels as compared to their older counterparts. As  $PaO_2$  is the main driving force in tissue oxygenation, low  $PaO_2$  levels will adversely affect tissue oxygenation and result in hypoxia.

Similarly, other factors like 2,3 DPG, temperature,  $H^+$  concentration, and  $CO_2$  which are common in sick newborns affect the oxyhemoglobin dissociation in a similar fashion (**Fig. 2**). Conditions which shift the oxygen dissociation curve to the left decreases the concentration of deoxygenated hemoglobin at a given  $PaO_2$ , and lowers the  $PaO_2$  at which cyanosis first appears. As shown in **Figure 2**, for a given  $PaO_2$  of 20 mm Hg,  $SaO_2$  in newborn is almost 50% as compared to almost 25% for adults. In contrast, acidosis, hyperthermia, or increased concentrations of adult hemoglobin shift the oxyhemoglobin dissociation curve to the right, thereby lowering oxygen affinity. As a result, for a given  $PaO_2$ , these conditions increase oxygen delivery to the tissues resulting in a greater concentration of deoxygenated hemoglobin, thus promoting the appearance of cyanosis at a much higher  $PaO_2$  levels (**Fig. 2**).

## CLINICAL PRESENTATION

### Peripheral Cyanosis

It is the bluish discoloration of extremities, but not the mucous membranes and tongue. It is due to increased oxygen extraction by the tissues that results from sluggish movement of blood through the capillary circulation. It is a transient finding in newborn (acrocyanosis) which usually resolves in 24–48 hours time. Other causes of cyanosis may include vasomotor instability (e.g., sepsis), vasoconstriction (sepsis, exposure to cold), venous obstruction, elevated venous pressure, polycythemia, and low cardiac output.

### Central Cyanosis

It is caused by reduced systemic arterial oxygen saturation. Normal newborn after birth may have central cyanosis and attain a preductal saturation of 80–85% and 85–95% only at 5 and 10 min, respectively. A markedly higher oxygen content in the upper (appearing pink) versus the lower part of the body or limbs (appearing blue) due to persisting right to left shunt through the patent ductus results in *differential cyanosis*, e.g., persistent pulmonary hypertension. *Reverse differential cyanosis* is said to exist when there is elevated lower limb saturation as compared to upper limb saturations. It can be seen in newborns having the following cardiac anomalies:

- Transposition of great arteries with abnormal pulmonary—aortic shunt due to left-sided obstructive lesions like

interrupted aortic arch, coarctation of aorta, or suprasystemic pulmonary vascular resistance.

- Total anomalous pulmonary venous connection shunting higher oxygenated right ventricular blood through patent ductus to systemic aorta.

## APPROACH TO CYANOSIS

A systematic approach to neonatal cyanosis starts with a detailed history assessing pregnancy, labor, and newborn risk factors, and physical examination. The possible causes of cyanosis in relation to history, examination and chest X-ray clues are listed in **Table 2**. Arterial blood gases help in determining the oxygenation, ventilation, and acid-base status of the infant. A normal  $PaO_2$  in a neonate with cyanosis should suggest either polycythemia or methemoglobinemia (a useful clue is the presence of a saturation gap—difference in oxygen saturation measured by pulse oximetry and arterial blood gas). An echocardiography would help in diagnosis of structural cardiac lesions or persistent pulmonary hypertension of the newborn (PPHN). Hyperoxia test is perhaps the most sensitive and specific tool in initial evaluation of newborn with suspected critical congenital heart disease.

**Table 2** Clues to diagnosis of cyanosis on history, physical examination and radiology

<i>Clues from maternal history</i>	<i>Possible etiology of cyanosis</i>
Diabetes	TTN, HMD, polycythemia, hypoglycemia, congenital heart defects (most common TGA)
Pregnancy induced hypertension	IUGR with increased risk of polycythemia, hypoglycemia
Asthma	TTN
Lupus	Congenital heart block
Drug abuse	Narcotic withdrawal
Lithium intake	Ebstein anomaly
Polyhydramnios	Tracheoesophageal fistula , congenital diaphragmatic hernia
Oligohydramnios	Pulmonary hypoplasia
Previous sibling with respiratory distress	Surfactant protein B deficiency, Group B streptococcal pneumonia
History of congenital heart disease in 1st degree relatives	Increase risk of congenital heart disease
<i>Labor and delivery</i>	
PROM/ PPRM	Sepsis, pneumonia
Chorioamnionitis	Sepsis
Meconium stained amniotic fluid	PPHN, meconium aspiration syndrome
Anesthesia/Analgesia	Respiratory depression, apnea
Cesarean Section	TTN
Perinatal asphyxia	Seizures, severe HIE
Birth trauma	Erb's palsy with phrenic nerve injury
<i>Time of onset of cyanosis</i>	
Onset soon after birth	TTN, HMD, MAS, CDH, CCAM
Onset hours after birth	Cyanotic heart disease
Cyanosis increased on crying	Cyanotic CHD, e.g., Tetralogy of Fallot
Cyanosis decreased with crying	Bilateral choanal atresia
Cyanosis with feeding	Esophageal atresia, severe esophageal reflux
<i>Clues from newborn examination</i>	
Prematurity	Apnea, HMD
Large for gestation	HMD, TTN, hypoglycemia
Small for gestation	Polycythemia, hypoglycemia
Abnormal heart rate	Arrhythmias
Loss of beat to beat variability	Severe sepsis/severe HIE
<i>Upper airway and respiratory system</i>	
Glossoptosis with micrognathia	Pierre-Robin syndrome
Stridulous breathing	Laryngotracheomalacia, subglottic stenosis, vocal cord paralysis
Barrel shaped chest	Meconium aspiration syndrome
Small and narrow appearing thorax	(Jeune's) Asphyxiating thoracic dystrophy
Supraclavicular and suprasternal retractions	Upper airway obstruction (laryngeal web, tracheal stenosis)
Intercostal and subcostal retraction	Diminished lung compliance (Pneumonia, HMD)
Distantly heard breath sounds	Pneumothorax, pleural effusion, atelectasis
Positive thoracic transillumination	Air leak syndrome
<i>Cardiovascular system</i>	
Abnormalities of heart rate	Arrhythmias
Diminished or absent distal pulses	Left sided obstructive lesion ( HLHS, IAA, coarctation of aorta)
Upper limb systolic blood pressure > 10 mm Hg higher than lower limb	Coarctation of aorta, aortic arch hypoplasia and interrupted aortic arch
Preductal and postductal saturation difference >10%	Right to left shunt (e.g. PPHN)
Hyperdynamic precordium	Sizeable left to right shunt

Contd...

Contd...

<i>Clue from examination</i>	<i>Possible etiology of cyanosis</i>
Precordial thrill	Moderate pulmonary or aortic outflow obstruction
Gallop rhythm	Left to right shunt or myocardial dysfunction
Ejection clicks	Pulmonary or aortic valvar stenosis
Single S2	Pulmonary stenosis or atresia, truncus arteriosus
Loud second heart sound with narrow split	Pulmonary hypertension
<i>Abdomen</i>	
Scaphoid abdomen	CDH
Abdominal distension and absent bowel sounds	Sepsis
<i>Central nervous system</i>	
Hypotonia	Severe asphyxia, IEM, sepsis
Hypertonia	Narcotic withdrawal
Seizures	Severe HIE, IEM
Apnea	Apnea of prematurity
<i>Clues from chest X-ray findings</i>	
Bell-shaped thorax	Severe hypotonia, neuromuscular disorder
Air leak	Pneumothorax, pneumomediastinum
Increased parahilar markings, with fluid in the horizontal fissure	TTN
Reticular granular pattern with air bronchogram and low lung volume	HMD
Fluffy infiltrates with areas of patchy atelectasis and hyperinflation	MAS
Honeycomb appearance of lung fields	Pulmonary interstitial emphysema
Opacity of lung field with shift of mediastinum on contralateral side	Pleural effusion or chylothorax
Opacity of lung field with shift of mediastinum on ipsilateral side	Lobar atelectasis
Decreased pulmonary vascular markings	TOF, pulmonary atresia, Ebstein anomaly
Increased pulmonary vascular markings	Truncus arteriosus, transposition of great arteries, obstructed TAPVC, HLHS
Elevation of the right hemi diaphragm > 2 intercostal spaces compared with left side	Diaphragmatic paralysis
Hyperinflated lung	Lobar emphysema, cystic lesions of lungs
Bowel gas in thorax	CDH
<i>Shape of heart</i>	
Normal heart size	Hypoglycemia, polycythemia, sepsis, shock
Small heart size	Hypovolemia, pulmonary interstitial emphysema, congenital lobar emphysema
Boot shaped	TOF, tricuspid atresia
Egg on string	TGA
Large globular heart	Ebstein anomaly
Cardiomegaly	Infant of diabetic mothers, cardiomyopathy, congestive cardiac failure
Snowman sign (Figure of 8)	TAPVC

**Abbreviations:** IUGR, intrauterine growth restriction; CCAM, congenital cystic adenomatoid malformation; PPROM, preterm premature rupture of membranes; PPHN, persistent pulmonary hypertension of the newborn; HIE, hypoxic-ischemic encephalopathy; TTN, transient tachypnea of the newborn; HMD, hyaline membrane disease; MAS, Meconium aspiration syndrome; HLHS, hypoplastic left heart syndrome; CDH, congenital diaphragmatic hernia; TOF, Tetralogy of Fallot; TGA, transposition of the great arteries; TAPVC, total anomalous pulmonary venous connection.

## Hyperoxia Test

To evaluate the possibility of fixed, intracardiac right to left shunt, arterial oxygen tension ( $\text{PaO}_2$ ) should be measured in room air (if tolerated) followed by repeat measurements with the patient receiving 100% inspired oxygen for at least 10–15 min by direct arterial puncture. The  $\text{SaO}_2$  (pulse oximeter) should not be used for the hyperoxia test as 100%  $\text{SpO}_2$  can be obtained with a  $\text{PaO}_2$  ranging from 80 mm Hg to 680 mm Hg. Arterial oxygen tension measurements should be made at both “preductal” and “postductal” sites to rule out the possibility of duct-dependent pulmonary to aortic shunting. An arterial  $\text{PaO}_2$  of more than 250 mm Hg on breathing 100% oxygen ( $\text{FiO}_2 = 1$ ) virtually eliminates the possibility of critical structural cyanotic heart disease and is termed as *passed hyperoxia test*. An arterial  $\text{PaO}_2$  of less than 100 mm Hg (“failed hyperoxia test”) with  $\text{FiO}_2 = 1$  in the absence of clear cut lung disease is virtually diagnostic of cyanotic heart disease with possible intracardiac right to left shunt. Infants who have arterial  $\text{PaO}_2$  between 100 mm Hg and 250 mm Hg with  $\text{FiO}_2 = 1$  may have structural heart disease with complete intracardiac mixing with increased pulmonary blood flow as seen in single ventricular physiology (hypoplastic left heart syndrome).

Neonates who fail a hyperoxia test have a high possibility of critical congenital heart disease with duct dependent systemic or pulmonary blood flow, and should be started on PGE1 (prostaglandin E1) infusion to maintain ductal patency until anatomic definition can be accomplished. Rarely, if a neonate becomes unstable soon after starting PGE1 infusion, obstruction to pulmonary venous return, (TAPVR) or obstruction to left atrial egress (TGA with intact ventricular septum; hypoplastic left heart syndrome with a restrictive foramen ovale or intact atrial septum) should be considered.

With the increased availability of bedside echocardiography in neonatal units, and the risks of exposing babies to 100% oxygen even for a brief time, the hyperoxia test should be used judiciously. **Table 3** provides a summary of findings that would help differentiate pulmonary, cardiac and neurologic causes of cyanosis.

After initial clinical evaluation, chest radiograph, ECG, and laboratory work-up (blood glucose, calcium, CBC, and septic

screen) and echocardiography (where feasible), it should be possible to arrive at an etiology (**Flow chart 1** provides an algorithm for cyanosis evaluation). Management requires initial cardiorespiratory stabilization, assuring hemodynamic stability, oxygen administration, and shifting to a neonatal intensive care unit for further management based on the clinical diagnosis.

### IN A NUTSHELL

1. Cyanosis is bluish discoloration of the tissues that results when the absolute level of reduced hemoglobin exceeds 3 g/dL.
2. Hypoxemia may or may not correlate with the degree of cyanosis.
3. The detection of cyanosis is earlier in a polycythemic child as compared to an anemic child.
4. Factors which shift the oxygen dissociation curve to the left may produce a significant fall in  $\text{PaO}_2$  for a given  $\text{SaO}_2$  as compared to factors which shift the curve to right.
5. Cyanosis will be detected at a lower  $\text{PaO}_2$  in newborns who have more fetal hemoglobin and less 2,3 DPG levels as compared to their older counterparts, hence are more prone for tissue hypoxia.
6. An arterial  $\text{PaO}_2$  of  $< 100$  mm Hg (“failed hyperoxia test”) on breathing 100% oxygen ( $\text{FiO}_2 = 1$ ) in the absence of clear cut lung disease is virtually diagnostic of cyanotic heart disease with possible intracardiac right to left shunt.
7. Neonates who fail a hyperoxia test have a high possibility of critical congenital heart disease with duct dependent systemic or pulmonary blood flow hence should be started on PGE1 infusion.

## Chapter 14.11

# Necrotizing Enterocolitis

Krishna Kumar Diwakar

Necrotizing enterocolitis (NEC) as an entity comprising of vomiting, abdominal distension, shock and intestinal hemorrhage was described for the first time by Mizrahi in 1965. NEC affects nearly 15% of very low birth weight (VLBW) infants and is considered a disease almost exclusive to the premature infant. Less than 15% of NEC occurs in late preterm or term infants.

The preterm neonate could be justifiably called the *reluctant enteral feeder*. The premature infant is supposed to be an in utero organism, with all its nutritional requirements being maternally synthesized and routed through the hematogenous channels. A structurally and physiologically immature intestine, when expected to undertake tasks, that it is ill designed for, naturally produces a recipe for damage and catastrophe.

## EPIDEMIOLOGY

The prevalence of NEC varies amongst populations. National Institute of Child Health and Human Development-Neonatal Research Network (NICHD-NRN) study from 2003 to 2007 found that the prevalence of NEC remained high (11%) among very premature infants (born at 22–28 weeks), while it has been observed to be lower in Canada and Europe. Some studies have reported male infants to have the more severe forms of the disease, though these have not been validated by most other studies. Population studies from India on NEC are few in number. In one such report, the incidence of NEC in babies less than 32 weeks gestation was 5.2%. A common scenario in the developing world is that of a VLBW infant, who in addition to being born premature has also been subjected to intrauterine growth retardation. To what extent the in utero compromise enhances the risk of NEC in the

late preterm infant remains unclear. The observation by Australian researchers of the gradual reduction in the prevalence of NEC in the post surfactant era provides impetus to further studies on the causal relationship between various factors and NEC.

## ETIOPATHOGENESIS

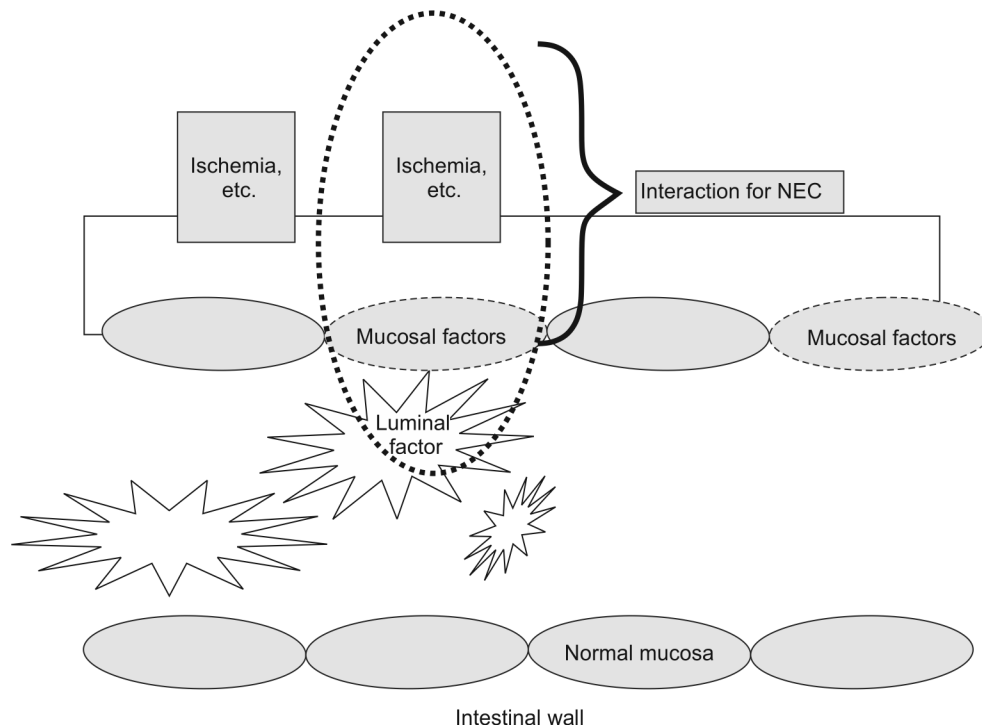

The inherent immaturity of the organ systems under the influence of varying contributory factors results in florid manifestation of NEC. Large epidemiological and more recent clinical studies have shown that previously held beliefs like, low Apgar scores, umbilical catheterizations, episodes of apnea and bradycardia, respiratory distress syndrome, anemia, hypothermia, hypoxic ischemic events, hypotension, indomethacin, etc., are less important as contributory factors for NEC. Exaggerated immunological responses at various stages of the disease contribute to the severity and morbidity of the disease. Complex mechanisms that include dysregulation of chemokines and cytokines like interleukin-6 (IL-6), angiopoietin-2, IL-RII have been observed in patients with NEC.

NEC manifests around the second week of life in preterm infants on oral feeds. It is seen to present earlier in late preterm and term neonates, implying that postmenstrual age (PMA) could influence the pathogenesis of the disease. Irrespective of the initiating mechanisms, the resultant ischemic hemorrhagic necrosis of the intestinal mucosa and the pathological progression of the injury highlight the morbidity of the disease. Prematurity is the single most important risk factor for the occurrence of NEC.

The pathogenesis could be broadly attributed to intestinal mucosal factors, luminal factors and vascular factors (**Fig. 1**). Needless to say, such a classification is an over simplified representation of a complex mechanism.

## Mucosal Factors

The status of the intestinal mucosa influences the normal mechanisms for intestinal epithelial repair. Factors like gestational immaturity, bacterial toxins, and secondary mucosal injury (ischemic or otherwise) have a negative influence on the normal

**Figure 1** Interaction of factors contributing to Necrotizing enterocolitis  
Abbreviation: NEC, necrotizing enterocolitis.

messengers of growth and repair, leading to a preponderance of inflammation, apoptosis and necrosis.

A compromised integrity at every layer of the intestinal mucosa is an inherent limitation of the preterm gut. Goblet cells secrete mucins that help to form a semipermeable barrier of the mucosa. Goblet cells density is increased by epidermal growth factors (EGFs). Lower levels of salivary EGF have been reported in preterm infants who develop NEC. Paneth cells are secretory enterocytes located at the base of the small intestinal crypts that release lysozyme, phospholipase A2, and antimicrobial peptides (defensins and cathelicidins), that help regulate the intestinal bacterial populations. Reduction in the Paneth cell functions seems to enhance the potential of pathogenic bacteria to precipitate NEC. Various inflammatory mediators and mechanisms are also affected by the inherent immaturity of the gut. Platelet-activating factor (PAF), an endogenous mediator is an important augmentor of the inflammatory responses. The enzyme PAF acetylhydrolase (PAF-AH) degrades PAF into the biologically inert lyso-PAF, and restricts uncontrolled progression of inflammatory response. The reduced PAF-AH levels in the neonate contribute to perpetuating PAF activity and aggravating an inflammatory response.

The cellular and molecular immaturity, combined with the diminished immunoglobulin A concentration and lower levels of mucosal enzymes (e.g., pepsin and proteases), and protective agents (lactoferrin) make the premature gut a highly vulnerable organ for bacterial and biochemical injury. The susceptible microenvironment of the gut is further vitiated by a higher gastric pH and decreased small bowel motility facilitates proliferation of pathogenic bacteria.

### Luminal Factors

This should be recognized as an interactive conundrum of substrate, toxins and microbes, with each component facilitating the actions of the other at various stages of the pathogenesis.

It has been claimed that more than 90% of all infants who develop NEC have received milk feeds. Preterm infants fed on formula milk have been observed to be at higher risk for NEC than those on human milk. Despite traditional beliefs, the rates and increments of feed have failed to show any increase in morbidity. Milk provides substrate for bacterial proliferation in the gut. The preterm gut is ill developed to digest and absorb the nutrients available in the feeds. The incompletely digested products (e.g., organic acids, short chain fatty acids, etc.) tend to damage the already vulnerable premature intestinal mucosa. The reduced peristalsis of the premature gut enhances the exposure of the intestinal mucosa to noxious substances.

Proliferating pathogenic bacteria, damage mucosa by their endotoxins and by interacting with the incompletely digested substrate to produce injurious by-products. No incriminating microbial species have been consistently isolated from infants with NEC. Signals from the microbial ligandins like endotoxins interact with the epithelial pattern specific receptors (e.g., toll-like receptors) and result in various mechanisms that could lead to either cytoprotective or destructive (apoptosis or inflammatory) response. Intestinal dilatation in the presence of dysbiosis (abnormal microbial colonization) could distort the normal signal transduction across the intestinal epithelial barrier and alter the pattern of normal growth and repair to that of inflammation, apoptosis and necrosis. Frequent and prolonged use of antibiotics could alter the natural intestinal microbial environment leading to proliferation of pathogenic bacteria.

Probiotics have been considered as a promising tool to promote growth of commensal bacteria in the gut. However, until more robust studies are available about the preferred bacterial strains, standardization of preparation, dosing, timing, duration of

therapy, response at different gestations, etc., probiotics cannot be recommended as a standard of care for preventing NEC.

The antimicrobial property of lactoferrin, is probably due to its iron sequestering property that makes iron unavailable for bacterial growth. Lactoferrin has broad microbicidal activity against gram-positive cocci, gram-negative bacilli, and *Candida* species. VLBW infants have low lactoferrin levels and this deficiency is exacerbated by delay in establishing enteral feeding.

### Vascular Factors

Vascular compromise of the intestinal circulation would certainly complicate an already compromised intestinal environment. Nitric oxide mediated responses have ensured low vascular resistance and high intestinal blood flow. Altered endothelial functions could alter this mechanism resulting in increased vascular resistance with the ensuing ischemic cascade progressing to mucosal necrosis. Though ischemia per se may not be a major triggering factor for NEC it would most certainly compound the morbidity. The earlier concern of umbilical catheters contributing to NEC has been fortunately found to be unsubstantiated.

While packed cell transfusions have been linked to the occurrence with NEC, the exact mechanism for this association is unclear. Transfusion associated NEC has, however, been reported to be associated with higher mortality.

### PATHOLOGY

Terminal ileum and colon are the common sites for NEC though the entire gastrointestinal tract could be affected in severe cases. On gross examination the bowel would appear distended and hemorrhagic. Features depend on the severity and stages of the disease. This would include subserosal collection of gas along the mesenteric border, gangrenous necrosis and perforation in the antimesenteric border. Various stages of healing would manifest as thickening of bowel wall, fibrinous adhesions and areas of stenosis.

Histological findings in NEC are mucosal edema, hemorrhage, and transmural necrosis. Other findings include acute inflammation, secondary bacterial infiltration, and collections of gas. Vascular thrombi are rare.

Spontaneous intestinal perforation (SIP) also called isolated intestinal perforation (IIP) is an entity that occurs earlier than classical NEC with a strong association with postnatal combined use of corticosteroids and indomethacin. This manifests commonly in the antimesenteric border of the terminal ileum. The clinical presentation is rather abrupt and is often a differential diagnosis for NEC. SIP is associated with lower levels of serum inflammatory cytokines and minimal intestinal inflammation and necrosis.

### CLINICAL PRESENTATION

For the caregivers of a preterm infant, there is nothing more satisfying than establishing complete enteral nutrition. Intolerance to feeds, distension or vomiting invariably raises the ubiquitous bogey of NEC. It often manifests in preterm infants by the second week of life, while on oral feeds. The age of onset of NEC is seen to be inversely related to the PMA with the disease manifesting earlier in late preterm and the occasionally term infants. While suspecting, NEC in these groups of infants, history should be sought of problems like perinatal stress that may affect mesenteric blood flow, intestinal anomalies (e.g., aganglionosis or atresia), congenital heart disease or maternal illicit drug use.

Compounding the differential diagnosis is a more recent entrant recognized as SIP or IIP. This is unrelated to feeding and occurs during the early days after birth, unlike the classical NEC that tends to occur around the second week of life. A combined usage of indomethacin and glucocorticoids, has been implicated

in SIP. SIP should be recognized as an entity different from NEC with different pathogenesis and thereby warranting management of strategies different from NEC.

### Clinical Features (Box 1)

The early signs of NEC are no different from that of sepsis. Lethargy, temperature instability, increasing heart rate, changes in perfusion as evidenced by increasing capillary refill time, alteration in glucose homeostasis, etc., are the subtle harbingers of NEC. These features become more profound as the disease progresses.

The initial gastrointestinal symptoms of NEC are subtle and appear no different from those of feed intolerance commonly encountered in most premature infants. It is here that the clinical vigil of the caregiver in detecting the subtle changes in the physiological characteristics like temperature instability pays rich dividends.

Gastric retention greater than 50% of the volume of feeds given over the previous 3–4 hours in a preterm infant, when associated with *unstable physiology* should always be considered as early NEC and therapeutic interventions initiated. While such an approach could lead to some false alarms, it is preferable to error on the side of caution where NEC is concerned. Increasing feed intolerance, bilious/*greenish* aspirates or vomiting, accompanied by progressive abdominal distension in a premature infants are clinical manifestation of the more established stages of NEC. Frank blood in stools (hematochezia), though considered pathognomonic of NEC is not an early sign. Abdomen would be tender, with guarding and occasionally tense. Gentle sensitive palpation could on occasion reveal a mass representing inflamed bowel with associated omental adhesions. Visible discoloration of the abdominal wall is an ominous sign, usually associated with gangrene and perforation of the gut.

Bowel sounds would be diminished to absent. This is a clinical feature useful to differentiate NEC from mechanical intestinal obstruction. Differentiating from paralytic ileus due to other causes, may however be more difficult during the early stages. Depending on the stage of the disease, the differential diagnosis of NEC could range from feed intolerance of the premature infant to SIP or gangrene of the gut due to other causes (**Box 2**).

## INVESTIGATIONS

### Radiological Examination

Plain X-ray of the abdomen could show a variety of presentations, depending on the severity of the disease. In the early stages, distended intestinal loops with thickened intestinal walls better appreciated in the cross-sectional view are the commonest presentation. Many neonatologists prefer to call this *Pre-NEC* stage, though the origin or justification of this terminology is unclear. If an X-ray repeated after a few hours shows a fixed loop of intestine, the suspicion of NEC would be more than justified. The presence of this *sentinel loop*, the so called *thumb print sign* in serial X-rays, represents the *local ileus* of that particular segment of the intestine.

Progression of the clinical stage of the disease is reasonably represented by the radiographic changes. This would range from paucity of intestinal gas shadows and fixed intestinal loop in the initial stages, to the more specific features of gas in the intestinal wall *pneumatosis intestinalis* (**Fig. 2**), and occasionally, gas in the portal vein.

Free-peritoneal gas, the ominous sign of intestinal perforation would be obvious if there is a massive collection. Selective radiological views should be taken when perforation is being sought for. The left lateral decubitus view may reveal gas collection below the diaphragm in relation to the liver, or a cross table view could show gas just beneath the abdominal wall (**Fig. 3**). It must

be remembered that minimal gas in the peritoneum may not be detected on X-ray, and absence of radiological features does not necessarily obviate the role of surgical management in NEC.

### BOX 1 Necrotizing enterocolitis staging based on Bell's stage

#### Stage I (Suspect)

- Clinical
  - *Systemic*: Temperature instability, lethargy, apnea, bradycardia
  - *Gastrointestinal manifestations*: Poor feeding, increasing pregavage residuals, emesis (may be bilious), mild abdominal distension
- Radiograph
  - Abdominal distension with mild ileus

#### Stage II (Definite)

- Clinical
  - All above signs and symptoms plus gastrointestinal bleeding; marked abdominal distension
- Radiograph
  - Significant intestinal distension with ileus, bowel wall edema, peritoneal fluid, unchanging or persistent bowel loops (*sentinel loop*)
  - Pneumatosis intestinalis, portal vein gas

#### Stage III (Advanced)

- Clinical
  - Above signs and symptoms plus deterioration of vital signs
  - Features of septic shock or marked gastrointestinal hemorrhage
- Radiograph
  - Earlier features plus pneumoperitoneum.

### BOX 2 Differential diagnosis of necrotizing enterocolitis

- Physiological feed intolerance of prematurity
- Gastroesophageal reflux
- CPAP belly
- Gastric retention/vomiting due to drugs like theophylline
- Malpositioned oro/nasogastric tube (e.g., yellow aspirate from duodenum)
- Paralytic ileus due to sepsis
- Intestinal obstruction due to structural abnormalities of the gastrointestinal tract
- Spontaneous intestinal perforation (syn. isolated intestinal perforation)
- Internal hernia.

**Figure 2** X-ray abdomen showing dilated loops of bowel and intramural gas—*pneumatosis intestinalis* (arrows)

**Figure 3** X-ray abdomen (cross table) showing presence of pneumoperitoneum

The caregiver must realize that NEC is a painful condition. Lifting up the infant vertically for the so called *erect* radiograph must be strongly discouraged. Handling and positioning of the infant must be done with the most gentle and humane touch.

*Ultrasonography* may be used to detect smaller volumes of free peritoneal gas and portal venous gas.

### Hematology

Hemoglobin may be low. Vasoconstriction and hemoconcentration secondary to third spacing of fluid may at times result in falsely reassuring levels of hemoglobin or hematocrit in an otherwise anemic infant. Neutrophilia or neutropenia, with shift to the left and thrombocytopenia are commonly encountered.

### Biochemistry

Metabolic acidosis could be the manifestation of the disease per se or that of acute kidney injury, a not uncommon complication of

NEC. Renal functions and electrolytes must be critically analyzed as the disease progresses. Hyponatremia is considered by many clinicians as an ominous sign.

### MANAGEMENT

Management of NEC starts from the moment the disease entity is suspected. Unfortunately, clinical features alone are far from adequate to diagnose NEC. The staging system described by Bell et al., in 1978 and subsequently refined (**Box 1**) has been used for the systematic description of NEC. However, other causes for perforation like SIP, vitiates the reliability of the Bell's criteria to confirm and grade the severity of NEC. The relative lack of correlation between the clinical presentation, radiological observation and the histopathological findings of the tissue makes the available staging system unreliable for deciding surgical intervention. Despite its limitations, this clinical and radiology based staging system has continued to be a guideline for planning treatment.

Supportive care and antibiotics are initiated, at the slightest suspicion of the disease. Astute clinical, radiological and laboratory evaluations at regular intervals are necessary to confirm the diagnosis of NEC and monitor its progression. Surgical intervention is resorted to if the disease progresses to the advanced stages (**Table 1**).

### Supportive Management

Bowel rest is the most important treatment to be initiated when one is suspecting NEC. The infant should be kept nil by mouth. Abdominal girth should be measured and serially monitored in the same planar circumference. Most experienced neonatal nurses mark parallel lines on the abdomen of the infant to ensure that girth measurement is always along the same path. Total parenteral nutrition is initiated until the infant is back to sustained and complete oral intake—a process best achieved by gradual increments over 7–10 days after clinical and radiological improvement.

*Gastric aspiration* at regular (conventionally 4th hourly) intervals should be done, and the volume and color of the aspirate to be noted. Significant nonbilious gastric residues (more than

**Table 1** Management of necrotizing enterocolitis

Presentation	Intervention	Investigations
Feed intolerance in at-risk infant, mild abdominal distension, some soft signs of sepsis	Keep nil by mouth Intravenous fluids Antibiotics	<i>X-ray abdomen:</i> Nonspecific <i>Blood investigations:</i> complete blood count, blood cultures, renal parameters, electrolytes
<i>Suspected NEC (Bell's stage 1)</i> Decreased activity Thermoregulatory instability Abdominal distension Increased gastric aspirates Sluggish or absent bowel sounds	<i>All the above plus:</i> Fluid resuscitation To consider inotropes TPN may be initiated	<i>X-ray abdomen:</i> Distended intestinal loop Abnormal pattern of intestinal gas Thickened intestinal wall Fixed/sentinel loop of intestine <i>Blood investigations:</i> Same as earlier plus blood gases for metabolic or respiratory acidosis
<i>Definite NEC (Bell's stage 2)</i> Green or yellow aspirates or evidence of gastrointestinal bleeds Tender abdomen, soft mass may be palpable (commonly in right lower quadrant of abdomen) Absent bowel sounds	<i>All the above plus:</i> Inotropes commenced, Supportive ventilation may be initiated	<i>All the above plus:</i> Pneumatosis intestinalis Gas shadow in the portal vein
<i>Advanced NEC (Bell's stage 3)</i> <i>All the above plus:</i> Increased morbidity Circulatory instability and shock Discoloration of abdominal wall	<i>All the above plus:</i> Ventilator support Surgical intervention	<i>X-ray abdomen:</i> Pneumoperitoneum <i>Blood investigations:</i> Same as above

Abbreviations: NEC, necrotizing enterocolitis, TPN, total parenteral nutrition.

1 mL/hour) are replaced with isotonic saline, while bilious residues are best replaced volume for volume by Ringer's lactate solution. As the infant's condition improves, the aspirates become clearer and gradually reduce to negligible levels.

One must remember that with the increasing abdominal girth, the infant would be having third space fluid losses. Additional boluses of saline or ringer lactate may be given over 30–60 min, with strict vigil for fluid overload. The aim is to ensure that perfusion is well-maintained to avoid hypoperfusion of the organs and pre-empt prerenal failure. The erratic dose response of dopamine with the possible risk of mesenteric vasoconstriction due to  $\alpha$ -adrenergic effect even at lower doses, has influenced some units to use alternative inotropic drugs such as epinephrine or even dobutamine when inotropic support is required.

*Ventilator support* may be required if there is acidosis, or progressive abdominal distension hampering normal respiration. This would also provide an opportunity for using narcotic analgesics to alleviate the pain associated with NEC.

*Antibiotics* have been traditionally started in all cases of NEC. The early stages of NEC are often difficult to differentiate from sepsis associated with paralytic ileus. It is also justifiable, as documented bacteremia has been reported in nearly 30% of NEC cases. Gram-negative bacteria like *Enterobacter* spp, *Klebsiella* spp, and *E. coli* constitute majority of bloodstream infections (BSI) in patients with NEC. NEC with concurrent BSI has been found to be associated with higher morbidity and requiring more surgical intervention. Further, the recovery of pathogenic bacteria from peritoneal fluid and the association of NEC with epidemic outbreaks of bacterial infections, justify initiating antibiotics early.

The common practice in most neonatal units, is to use triple drug combination of (1) a penicillin or third-generation cephalosporin; along with (2) an aminoglycoside; and (3) metronidazole. The antibiotics are generally continued till clinical recovery is evident, with the infant tolerating oral feeds usually by 7–14 days.

### Monitoring

All physiological parameters like blood pressure, heart rate, capillary refill time, respiratory parameters, etc., must be regularly evaluated and corrective interventions undertaken. Radiological assessment at 6–8 hourly intervals, is necessary to monitor the progress of the disease. Once clinical and radiological improvement commences, the frequency of these investigations can be reduced. The *pneumatosis intestinalis* tends to disappear over 3–4 days and heralds the gradual recovery process.

Thrombocytopenia and hyponatremia herald ominous outcome. Sudden onset of hyperglycemia is often seen when peritonitis occurs due to transmural spread of inflammation or perforation of viscus. This is often accompanied by deterioration of other physiological parameters. It must be remembered that pneumoperitoneum need not be always radiologically evident.

### Surgical Intervention

The pediatric surgeon is an integral part of the treating team. The timing of surgical intervention is crucial for optimally salvaging the viable bowel. While pneumoperitoneum is an unambiguous decision for surgical intervention, it must be remembered that all perforation may not always be radiologically evident. Therefore, one should be vigilant for other signs of bowel necrosis heralded by deteriorating clinical condition, despite medical management, ascites, palpable mass per abdomen or intestinal obstruction. We have observed a sudden onset of hyperglycemia, in an otherwise euglycemic patient, to be an indicator of peritonitis or perforation.

The specifics of surgical procedures are beyond the purview of this chapter. However, surgical interventions can be summarized as below:

- *Primary peritoneal drainage (PPD)*: This is preferred in critically ill infants below 1,000 g. It can be done under local anesthesia at the bedside.
- *Laparotomy*: There could be different strategies during laparotomy.
- Resecting the necrotic bowel with proximal enterostomy and distal mucus fistula, followed by reanastomosis after 8–12 weeks.
- Resection and primary anastomosis, if only a short segment is involved.
- *Second look approach*: When there is extensive necrosis observed on laparotomy, drains are placed and the abdomen is closed, with the intention of a *relook*. Laparotomy is undertaken again after 2–3 days to enable identification and resection of the segment of the gut that is unambiguously necrotic. The aim is to preserve the maximal length of the viable intestine.

In critically ill preterm infants, the outcome of both PPD and laparotomy has been found to be similar. Proponents for both strategies continue to advocate their preferred method of treatment. Primary peritoneal drainage has not been beneficial when IIP has been the confounding diagnosis.

### COMPLICATIONS

Complications could occur during the acute stage of the disease or may present as late complication. Commonly observed acute complications are:

- Infection linked problems like sepsis, meningitis, peritonitis, abscess formation.
- Disseminated intravascular coagulation.
- Respiratory and cardiovascular—hypotension, shock, and respiratory failure.
- Metabolic complications—metabolic acidosis, hypoglycemia, hyperglycemia, hyponatremia.
- Acute kidney injury.

Complacency after recovery from the acute illness would be ill-advised. While some areas of intestinal narrowing recover, intestinal stricture could persist in 9–36% of NEC. Interestingly, this is unrelated to the severity of the acute disease. Colon is the most common site for stricture formation, though strictures could occur at any part of the intestine or even at multiple sites in the same patient. Risk of developing short bowel syndrome after operative management of NEC was higher in infants below 750 g. As expected, greater percentage of bowel resection and requirement of jejunostomy were associated with a risk for short bowel syndrome. Growth retardation and neurodevelopmental delay have also been reported in infants affected by the more severe forms of NEC.

### IN A NUTSHELL

1. Prematurity is the single most important risk factor for NEC in the newborn.
2. No single clinical sign is pathognomonic of NEC in the newborn; a high index of suspicion is required in sick preterm neonates for NEC.
3. *Pneumatosis intestinalis* is the most classical radiological finding of NEC in newborn.
4. Probiotic therapy has limited role in prevention of NEC.
5. Management of NEC is essentially supportive with intense monitoring for disease progression.

## Chapter 14.12

# Retinopathy of Prematurity

Ashish Jain, Veeraraja B Sathenahalli,  
Karobi Lahiri Coutinho

Retinopathy of prematurity (ROP), previously known as retrolental fibroplasia is a vasoproliferative disorder of immature developing retina of preterm infants. Its presentation varies from mild, transient changes which regress spontaneously to severe progressive vasoproliferative changes leading to scarring and eventually retinal detachment. ROP is one of the most important preventable causes of childhood blindness in both industrialized and developing countries. Emergence of ROP in recent time can be attributed to the increasing preterm births that get improved and advanced care leading to increased survival, but this comes at a cost of many unwanted consequences among which ROP is one. Hence, world over industrialized countries have witnessed two epidemics of ROP. First in the 40s and 50s, affecting largely premature babies in the US and Europe due to increased use of unregulated oxygen in these babies. However, this epidemic ended with implementation of controlled oxygen administration. Improved understanding of the risk factors for ROP and improving neonatal care with invention of newer modalities of treatment resulting in increased survival rates of premature babies paved way for the second epidemic in 1970s in industrialized countries. Now third epidemic of ROP is occurring in middle-income countries namely Latin America, Former Socialist Economies, India and China. Increasing rate of preterm birth, increased access to health-care facilities, high rates of ROP requiring treatment in these preterm babies and inadequate screening program are contributing factors for the third epidemic. Timely screening, initiation of treatment and proper follow-up can prevent blindness and reduce the morbidity associated with ROP.

## EPIDEMIOLOGY

Retinopathy of prematurity (ROP) causes blindness in almost 50,000 children worldwide. Some of the Indian studies have reported an incidence of 20–50% among screened neonates. However, recent studies report a lower rate of 20–30%. According to early treatment for retinopathy of prematurity study (ETROP) trial, a multicenter trial, 68% of ROP (any stage) was reported among neonates less than 1,250 g, this was comparable to previously reported data by another multicenter trial, cryotherapy-ROP (CRYO-ROP, 65.8%).

## DEFINITION

Retinopathy of prematurity is a disorder of the immature developing retinal vasculature characterized by cessation of the normal progression of newly forming vessels (vasculogenesis), followed by the development of new abnormal blood vessels (neovascularization) which eventually heals by completely involuting with normal vascularization of the retina (regression) or progresses to a chronic phase (cicatrical ROP) with scarring, retinal detachment and visual loss.

## ETIOLOGY

Following risk factors make the immature developing retina of premature infant susceptible to changes responsible for development of ROP.

- Prematurity
- Low birth weight

- Small for gestational age
- Delivery room resuscitation involving chest compression and/or medications
- Respiratory distress syndrome/surfactant therapy/oxygen therapy for more than 24 hours
- Severe intraventricular hemorrhage (IVH, Grade 3 or Grade 4)
- Patent ductus arteriosus requiring pharmacological or surgical closure
- Culture-positive sepsis or culture-negative sepsis treated with antibiotic therapy for more than 5 days
- Documented necrotizing enterocolitis
- Multiple blood transfusions and/or exchange transfusion
- Pneumothorax
- Hypotension requiring vasopressor therapy.

## PATHOGENESIS

Various theories have been proposed for the pathogenesis of ROP. The important ones are the Classical theory and the Gap junction theory.

The *Classical theory* hypothesized that ROP occurred in two phases:

1. *Hyperoxic phase* It occurs immediately after birth due to exposure to hyperoxic environment. This leads to retinal arteriolar constriction, irreversible vaso-obliteration and dissolution of the retinal capillary endothelial cells.
2. *Hypoxic phase* On withdrawal of the hyperoxic environment, an ischemia induced vasoproliferative response was seen, resulting in ROP.

The *Gap Junction theory* is based on the activity of mesenchymal spindle cell precursors of retinal capillaries. The precursor cells migrate from optic disc to the junction between vascular and avascular retina to form a new capillary network. Under hyperoxic conditions, abnormal gap junctions appear between adjacent spindle cells and this interferes with normal cellular migration and vascular formation. The angiogenic factors secreted by these mesenchymal cells may in turn trigger a neovascular response.

The current understanding incorporates both theories. Hence, pathogenesis of ROP can be divided into two sequential phases:

1. *Phase 1 Hyperoxia-vasoconstriction*: This phase is characterized by cessation of vascular endothelial growth factor (VEGF) driven vessel growth because of exposure of the premature infant to hyperoxic condition immediately after birth. The consequent vascular endothelial obliteration results in retinal vessel obliteration.
2. *Phase 2 Hypoxia-vasoproliferation*: On termination of phase of hyperoxia, retinal ischemia occurs, a high metabolic demand of the developing vessels causes hypoxia driven VEGF expression now resulting in neovascularization (hallmark of Phase II ROP). VEGF is a promoter of angiogenesis upregulated by hypoxia. Insulin-like growth factor 1 (IGF-1) is produced by placenta in late second and third trimester by an oxygen-independent mechanism. IGF-1 participates in the regulation of VEGF within the retina. Its absence due to premature birth plays a major role in the pathogenesis of ROP, because VEGF is then produced by the ischemic retina without any regulation, resulting in the abnormal angiogenesis.

## CLASSIFICATION OF RETINOPATHY OF PREMATURE

The international classification of retinopathy of prematurity (ICROP) by Flynn was first published in 1984 and expanded in 1987. The original ICROP dealt with the early phases of the

disorder and was based on several key observations essential in describing the retinopathy. These included (1) the location of retinal involvement by zone, (2) the extent of retinal involvement by clock hour (**Fig. 1**), (3) the stage or severity of retinopathy at the junction of the vascularized and avascular retina, and (4) the presence or absence of dilated and tortuous posterior pole vessels (plus disease). This was revisited in 2005 to include (1) the concept of a more virulent form of retinopathy observed in the tiniest babies [aggressive posterior ROP (AP-ROP)], (2) a description of an intermediate level of plus disease (preplus) between normal posterior pole vessels and frank plus disease, and (3) a practical clinical tool for estimating the extent of zone I in addition to old classification (**Table 1**). The definitions for some of the terms used in the classification are as under:

- **Preplus disease** This spectrum of ROP is characterized by abnormal tortuosity and dilatation of the posterior vessels. The abnormality may not account up to plus disease but demonstrates more venous dilatation and arterial tortuosity than normal. This may progress to plus disease anytime.
- **Aggressive posterior ROP** This is an uncommon, rapidly progressing severe form of ROP previously known as *type II ROP* and *Rush disease*. It is characterized by its posterior location, prominence of plus disease and the ill-defined nature of retinopathy. If untreated, it usually progresses to stage 5 ROP. Most commonly observed in zone I, but may also occur in zone II. Another important feature of AP-ROP is that it usually does not progress through the classic stages 1–3. It may appear as only a flat network of neovascularization at the deceptively featureless junction between vascularized and nonvascularized retina which may be overlooked by an inexperienced observer. The extend is typically circumferential. Use of 20D condensing lens instead of regular 25D or 28D during indirect ophthalmoscopy may help in distinguishing this deceptively featureless neovascularization of AP-ROP.
- **Threshold disease** According to CRYO-ROP study, this is defined as a morphologic change beyond which the incidence of unfavorable outcome is more than 50%. It translates into the presence of stage 3 with plus disease in zone I or zone II, extending in 5 or more contiguous or 8 cumulative clock hours.
- **Prethreshold disease** Presence of less than threshold disease in zone I, or stage 2 plus disease in zone II, or stage 3 (without plus) disease in zone II, or stage 3 plus disease with extent

**Figure 1** Diagram of retina describing the zone and extent of retinopathy of prematurity according to ICROP. The retinal changes observed during screening examinations should be recorded according to the above figure

less than that for threshold disease. Now this is the stage where the laser therapy is considered.

## EARLY IDENTIFICATION AND SCREENING

Retinopathy of prematurity occurs in a sequential nature of progression that depends on the gestational age at birth and the postnatal age of the baby. When these babies are examined by an experienced ophthalmologist on a scheduled basis, the same can be identified before it progresses to a severe stage. Thus, timely screening and treatment has a proven benefit of reducing the risk of visual loss. The goal of an effective ROP screening program is to identify the infants who could benefit from treatment and make appropriate recommendations on the timing of future screening and treatment interventions. Because unchecked ROP can lead to permanent blindness, it is important that all at-risk infants be screened in a timely fashion, recognizing that not all infants require treatment.

## Screening for Retinopathy of Prematurity

### Neonates to be Screened for Retinopathy of Prematurity

The ROP screening should be undertaken in the following at-risk neonates:

- Neonates with a birth weight of less than and equal to 1,500 g or gestational age of 30 weeks or less (as defined by the attending neonatologist).

**Table 1** International classification of retinopathy of prematurity (ICROP)

Location	Zone I	Circle with optic nerve at its center and a radius of twice the distance from optic nerve to macula
	Zone II	Concentric circle from edge of zone I to ora serrata nasally and equator temporally
	Zone III	Lateral crescent from zone II to ora serrata temporally
Severity	Stage 1	Presence of thin white demarcation line separating vascular from avascular retina ( <b>Fig. 2</b> )
	Stage 2	Addition of depth and width to the demarcation line of stage 1, so as the line becomes ridge ( <b>Fig. 3</b> )
	Stage 3	Presence of extraretinal fibrovascular proliferation with abnormal vessels and fibrous tissue extending from ridge to vitreous ( <b>Fig. 4</b> )
	Stage 4	Partial retinal detachment not involving macula (4A) and involving macula (4B, <b>Fig. 5</b> )
	Stage 5	Complete retinal detachment ( <b>Fig. 6</b> )
Plus disease	Presence of dilatation and tortuosity of retinal vessels at posterior pole of eye. Also associated with papillary rigidity and vitreous haze	
Extent	Extent of retinopathy of prematurity described in 30° clock hours (a total of 12-hour clock of 30° each)	

**Figure 2** Stage 1–2 retinopathy of prematurity showing thin white demarcation line separating vascular from avascular retina

**Figure 3** Stage 2 retinopathy of prematurity; the line becomes ridge

**Figure 4** Stage 3 retinopathy of prematurity showing extraretinal fibrovascular proliferation with abnormal vessels and fibrous tissue extending from ridge to vitreous

**Figure 5** Stage 4B retinopathy of prematurity showing partial retinal detachment involving macula

**Figure 6** Stage 5 retinopathy of prematurity showing complete retinal detachment

- Selected infants with a birth weight between 1,500 g and 2,000 g or gestational age of less than 30 weeks with an unstable clinical course, including those requiring cardiorespiratory support.
- Infants believed by their attending pediatrician or neonatologist to be at high-risk for ROP such as prolonged oxygen therapy, repeated episodes of apnea of prematurity, anemia needing blood transfusion, neonatal sepsis, hypotension and poor weight gain.

The above criteria were laid down by the American Academy of Pediatrics. However, in India the gestation of the neonate is not always known or accurate; in addition, ROP has been reported in larger babies (1,500–2,000 g). Hence, the National Neonatology Forum of India (NNF) recommends screening of neonates less than 34 weeks and/or birth weight less than 1,750 g.

Despite appropriate timing of examinations and treatment, a small number of infants at risk progress to poor outcomes. The initiation of acute-phase ROP screening should be based on the infant's postmenstrual age (PMA, **Table 2**). The onset of serious ROP correlates better with PMA (gestational age at birth plus chronologic age) than with postnatal age. Progression of ROP follows a distinct timeline. Hardly any ROP is detected before 32 weeks of PMA. The median age at detection of stage 1 ROP is

**Table 2** Timing of first eye examination based on gestational age at birth

Gestational age at birth (week)	Age at initial examination (week)	
	Postmenstrual	Chronologic
22	31	9
23	31	8
24	31	7
25	31	6
26	31	5
27	31	4
28	32	4
29	33	4
30	34	4
Older gestational age, high-risk factors		4

34 weeks. Threshold ROP appears at 34–38 weeks. Vascularization is complete by 44 weeks of gestation. Therefore, critical phase (Window) is between 34 weeks and 38 weeks, when the infant is likely to reach the threshold stage of disease and may require treatment for prevention of blindness.

### First Retinopathy of Prematurity Screen

First screening examination is to be carried at 32 weeks of PMA or 4 weeks of postnatal age, whichever is later. It has been well documented that VLBW babies, may develop early AP-ROP. This is relatively common in Indian babies and needs early screening. Hence, the NNF India recommends that the first screen should be performed not later than 4 weeks of age in neonates more than 28 weeks of gestation. Infants less than 28 weeks or less than 1,200 g should be screened early at 2–3 weeks of age, to enable early identification of AP-ROP.

### Follow-up Retinopathy of Prematurity Screens

Follow-up examinations should be recommended by the examining ophthalmologist on the basis of retinal findings classified according to the revised ICROP. The following schedule is suggested:

#### 1 week or less follow-up:

- *Immature vascularization:* Zone I, no ROP
- Immature retina extends into posterior zone II, near the boundary of zone I
- *Stage 1 or 2 ROP:* Zone I
- *Stage 3 ROP:* Zone II
- The presence or suspected presence of AP-ROP.

#### 1–2 week follow-up:

- *Immature vascularization:* Posterior zone II
- *Stage 2 ROP:* Zone II
- *Unequivocally regressing ROP:* Zone I.

#### 2 weeks follow-up:

- *Stage 1 ROP:* Zone II
- *Immature vascularization:* Zone II, no ROP
- *Unequivocally regressing ROP:* Zone II.

#### 2–3 weeks follow-up:

- *Stage 1 or 2 ROP:* Zone III
- *Regressing ROP:* Zone III.

### Termination of the Retinopathy of Prematurity Screen

The retinal screening examinations may be terminated based on PMA or retinal findings. Findings that suggest that examinations can be terminated include the following:

- Zone III retinal vascularization attained without previous zone I or II ROP (if there is examiner doubt about the zone or if the PMA is less than 35 weeks, confirmatory examinations may be warranted).
- Full retinal vascularization in close proximity to the ora serrata for 360°—that is, the normal distance found in mature retina between the end of vascularization and the ora serrata. This criterion should be used for all cases treated for ROP solely with bevacizumab.
- Postmenstrual age of 50 weeks and no prethreshold disease (defined as stage 3 ROP in zone II, any ROP in zone I) or worse ROP is present.
- Regression of ROP (care must be taken to be sure that there is no abnormal vascular tissue present that is capable of reactivation and progression in zone II or III).

On simplifying the above recommendations, ROP screening should be continued till complete vascularization of retina without any ROP, or if the ROP has shown regression which happens at around 40–44 weeks of PMA.

### Retinopathy of Prematurity Screen Procedure

Screening is best done in the neonatal intensive care unit under supervision of attending pediatrician/neonatologist. Dilatation of pupils is done with phenylephrine 2.5% and tropicamide 0.5–1%. One drop of tropicamide is instilled every 10–15 minutes up to 4 times starting 1 hour before the scheduled time for examination. This is followed by phenylephrine, just one drop before examination. Phenylephrine is available in 10% concentration; it should be diluted 4 times before use in neonates. Repeated instillation of phenylephrine is avoided for the fear of hypotension. If pupils are not dilating despite administration of mydriatic drops, AP-ROP should be suspected.

The examination is done by indirect ophthalmoscopy using 20D or 28/30D lens by an experienced ophthalmologist. A topical anesthetic drop like proparacaine is used to avoid pain during the procedure; a wire speculum is inserted to keep the eyelids apart. The examination progresses from anterior segment to posterior segment. Anterior segment is examined for corneal clarity, anterior chamber depth, pupillary dilation, lens status, and media clarity. Then the posterior pole is visualized to look for plus disease. This is essential because sclera indentation can alter the vascular dilation and tortuosity and cause confusion in interpretation of plus disease. Then the peripheral retina is examined in each clock hour to assess the zone and stage of ROP. Gentle indentation with a pediatric depressor helps to stabilize the globe, visualize the periphery and contrast the details. The findings should be documented after each examination on a ROP chart as per the recommendations of ICROP, mentioning zone, stage and extent in terms of clock hours of any ROP and the presence of any preplus or plus disease. The timing of next visit should also be mentioned at the same time.

Proper precaution should be taken while screening the baby. This includes maintenance of asepsis; the examination should be as brief as possible to avoid short-term effects on blood pressure, heart rate and respiratory function in the premature baby. Discomfort to the baby can be minimized by administering oral sucrose just before examination, pretreatment of the eyes with a topical proparacaine and swaddling the baby. It is better to skip a feed just before the examination as there are chances of vomiting and aspiration.

### RetCam Screening

The use of digital photographic retinal images that are captured and sent for remote interpretation is a developing approach to ROP screening. It has been evaluated as an alternative to indirect ophthalmoscopy screening. The images captured can be stored, transmitted to expert, reviewed, analyzed and sequentially compared over time and are

useful for telemedicine purposes. It has an advantage of eliminating interobserver variability and is also a useful teaching tool. The high cost, lack of trained individuals and diagnostic inaccuracy are the limitations of this novel approach. RetCam in comparison to IO has variable sensitivity but good specificity.

## DIFFERENTIAL DIAGNOSIS

Following diseases mimic ROP:

- Familial exudative vitreoretinopathy
- Persistent hyperplastic primary vitreous/persistent fetal vasculature syndrome
- Norrie disease
- Incontinentia pigmenti
- Osteoporosis-pseudoglioma syndrome.

## MANAGEMENT

Therapy for ROP is directed at treating the underlying pathogenesis by decreasing VEGF levels (specifically VEGF-A), either by completely ablating the peripheral avascular retina that produces the VEGF (LASER therapy/cryotherapy) or by inactivating VEGF by binding it after its production (anti-VEGF therapy).

### Proven Methods (Cryotherapy/LASER therapy)

Standard treatment of ROP in the initial period was by cryotherapy. Treatment of ROP shifted from cryotherapy to light amplification by stimulated emission of radiation (LASER) ablation in 1990s as cryotherapy was very painful, required ventilation during procedure, lacked approach to posterior retina and left a residue of myopia and retinal detachment even after such amount of traumatic procedure. Laser ablation, though a less painful procedure, lacks the other disadvantages of cryotherapy.

Laser ablation involves ablation of peripheral avascular retina so as to prevent the hypoxic drive of retina which produces VEGF causing progression of ROP. This prevents the progression and causes the regression of an established ROP. ROP retina should be avoided as it will cause torrential bleeding inside due to its abnormal vasculature.

According to ETROP, indications of retinal ablation are:

- Zone I, any stage ROP with plus disease
- Zone II, stage 3 ROP without plus disease
- Zone II, stage 2 or 3 ROP with plus disease.

The above stages are included in type I ROP. They include threshold ROP and subset of prethreshold ROP likely to benefit from early treatment.

Type 2 ROP includes:

- Zone I, stage 1 or 2 ROP without plus disease
- Zone II, stage 3 ROP without plus disease.

The above stages require continued serial examinations to follow their progression.

### Newer Strategies (Bevacizumab)

Bevacizumab is a humanized recombinant antibody that inhibits the biological activity of VEGF. It has been widely used for ocular angiogenesis disorders like age-related macular degeneration, proliferative diabetic retinopathy and neovascular glaucoma. An intravitreal injection of bevacizumab demonstrated reduced neovascular activity. In a small case series, when used in stage 3 ROP (acute phase ROP including AP-ROP), it temporarily slowed vasculogenesis and permanently halted angiogenesis. It has the advantage that retinal vessels continued grow as opposed to permanent destruction of the same with laser therapy. But it is yet to be recommended for routine use in neonates with ROP as data regarding serious systemic adverse effects of intravitreal injection are lacking. It may be used only when laser photocoagulation fails and

after taking informed consent from the parents. Another anti-VEGF drug, Pegaptanib sodium is under study and is yet to be studied under large trials before its approval for use. Other newer strategies for treatment of ROP include IGF-I, granulocyte colony stimulating factor, c-Jun-N-terminal kinases (JNK) inhibitors and gene therapy.

## Surgical Management

Surgical management consists of vitreoretinal surgery for the treatment of retinal detachment and includes scleral buckling and vitrectomy.

## SEQUELAE

Timely screening and treatment of ROP reduces vision loss but sequelae can occur even in successfully treated infants. Thus, patients should be followed closely at regular intervals both in the acute stages and in the long-term. Following are the most common sequelae seen in eyes treated for ROP:

- *Visual function:* Reduction in visual acuity is seen. Infants with advanced ROP were found to have visual acuity less than 20/200.
- *Strabismus:* It is seen in up to 40% of babies varying from mildest stages to advanced stages.
- *Myopia:* It is the most common sequelae seen in up to 50% of cases. May cause anisometropia on long run.
- *Amblyopia:* A result of strabismus/anisometropia, frequent screening will help in early identification and requires treatment in the form of refractive correction, occlusion therapy or surgery.
- *Glaucoma:* Seen in advanced stages and is secondary to narrowing of anterior chamber due to retinal contraction causing anterior displacement of lens-iris diaphragm.
- *Retinal detachment:* One of the most common long-term sequelae seen in up to 25% of cases.

## PREVENTION

Retinopathy of prematurity is a preventable disease to a significant extent. The following methods may help in reducing the risk of development of ROP:

- *Judicious oxygen therapy:* Oxygen as drug is a double-edged sword. It should be administered in desired range of concentration to avoid hypoxia and hyperoxia. It is advised that oxygen saturation of the baby should be monitored using pulse oximetry. The oxygen saturation should be maintained between 90% and 93%. PaO<sub>2</sub> should be maintained between 50 mm Hg and 70 mm Hg.
- *Permissive hypercapnia:* Hypocapnia is a risk factor for ROP. By allowing permissive hypercapnia, i.e., 50–60 mm Hg when the pH is above 7.25, a lower ventilatory setting can be maintained minimizing the tendency for progression to chronic lung disease, an oxygen dependent disease.
- *Judicious use of blood transfusions:* Red blood cell (RBC) transfusion is a risk factor as it transfuses adult hemoglobin with low oxygen affinity; it ends up delivering a higher amount of oxygen to retinal tissues causing hyperoxia. Thus packed RBCs should be transmitted only when indicated.
- *Strict clinical monitoring:* Low and high blood pressure are also risk factors for ROP. These situations can be avoided by strict clinical monitoring.
- *Vitamin E supplementation:* Vitamin E deficiency predisposes to ROP. Thus vitamin E supplementation is advised in VLBW babies.
- *Prenatal steroids:* Use of prenatal steroids helps in prevention of ROP by preventing respiratory distress of newborn, IVH and preventing acute illnesses of the preterm infants which are risk factors for ROP.

### IN A NUTSHELL

1. Retinopathy of prematurity, a disorder of immature developing retina, characterized by vasocessation followed by neovascularization, is one of the leading preventable causes of blindness in developing countries.
2. Prematurity and low birth weight are the main risk factors associated with ROP.
3. Vascular endothelial growth factor and IGF-1 play a key role in the pathogenesis of ROP.
4. Babies to be screened are infants with a birth weight of less than and equal to 1,500 g or gestational age of 30 weeks or less (as defined by the attending neonatologist) and selected infants with a birth weight between 1,500 g and 2,000 g or gestational age of more than 30 weeks when associated with risk factors or to be considered when attending neonatologist thinks they are at high-risk.
5. According to Indian literature, first screening examination should be carried at 32 weeks of PMA or 4 weeks of postnatal age, whichever is later.
6. The findings of indirect ophthalmoscope should be recorded and classified according to the recommendations of ICROP.
7. Severity and staging of ROP determine the schedule of follow-up examinations.
8. Retinopathy of prematurity screening should be continued till complete vascularization of retina without any ROP, or if the ROP has shown regression which happens at around 40–44 weeks of PMA.
9. Treatment of ROP mainly aims at reducing the levels of VEGF. Retinal ablation of avascular retina is the mainstay of therapy.
10. Type I ROP, i.e., zone I—any stage ROP with plus disease, zone II—stage 3 ROP without plus disease and zone III—stage 2 or 3 ROP with plus disease are the indications for laser ablation.

## Chapter 14.13

# Neonatal Transport

Neelam Kler, Anup Thakur

Organized emergency neonatal transport systems are an important component of modern perinatal care. The aim of all neonatal transport teams is to transport an infant in a well-stabilized manner and this can be achieved by timely, organized, comprehensive care by the health-care team. Ideally, mothers with identified high-risk pregnancies should deliver in tertiary level perinatal facilities for comprehensive maternal and newborn care. In utero transfer is therefore undoubtedly the safest means of transfer; however problems of prematurity, perinatal illness and congenital malformations are often unanticipated, resulting in a continued need for transfer of these high-risk infants after birth.

Stabilization of newborn before and during transportation has been shown to improve the condition of newborn in terms of temperature, blood glucose, oxygenation and blood pressure. However, most of neonatal transports in our country are self transport without any pretreatment stabilization or care during transport. The consequences of such disorganized transports are often grave with most of these newborns being transported cold, blue and hypoglycemic. 75% of the babies transferred this way have serious clinical implications.

In India, antenatal care is inadequate and majority of the deliveries still occur at home (approximately 60% in rural areas as per National Family Health Survey 3). Thus, the problem of shifting sick neonates born in the community is compounded by a virtually nonexistent neonatal transport system. As a result most of the referred neonates reach the hospital in a critical state with 5-fold higher mortality risk as compared to those delivered in hospital or transferred in stable condition.

## REGIONALIZATION OF NEONATAL HEALTH-CARE

Neonatal transport programs require appropriate referral systems, management structures and trained transport personnel. They need to utilize transport equipment, address transport logistics and have a quality improvement program. Local factors such as geography, population density and organization of perinatal services affect the manner in which different transport programs function. There are various regionalized neonatal transport systems distributed all over the world. Among them, the popular ones are the New South Wales Emergency Transport System (NETS), various regionalized transport systems in United Kingdom and in United States of America. Similarly in India, Tamil Nadu, Madhya Pradesh and Gujarat are the other states where regionalized neonatal transport services are being initiated.

## ORGANIZED VERSUS SELF-TRANSPORT

Organized transport service provides almost the same level of monitoring and the quality of care during the transport that is available in an advanced NICU. Mechanical ventilation, multiple fluid infusion therapy and cardiorespiratory monitoring should be inherent in such services. In India, currently no dedicated neonatal transport service is available and most sick neonates are transferred by their parents or paramedical personnel either in private vehicles or poorly equipped ambulance. There is enough data to suggest that transport by a skilled organized team reduces neonatal mortality and morbidity. In a retrospective analysis done in a regionalized transport network in and around 250 km of Hyderabad, biochemical and temperature disturbances were

more common in babies transported on their own as compared to specialized neonatal transport service. Neonates transported by the hospital team had significantly higher survival as compared to those who came on their own.

## CLINICAL PROFILE OF TRANSPORTED BABIES

Common clinical reasons for transporting neonates include prematurity, hyaline membrane disease, sepsis and birth asphyxia. In India, the onus of transport usually lies with the parents, who are barely informed about the condition of their baby and the indications of transfer. In a recent study in India by Dalal et al., pretransport stabilization was done only in 37% of neonates and hypothermia, hypoxia, poor perfusion, hypoglycemia was observed in 55%, 27.4%, 23.4% and 20.6% of neonates respectively. Singh et al. noted a higher mortality of 56.2% in transported neonates as compared to an overall mortality of 26.3%. The neonates were usually brought to the emergency department wrapped in cotton (24.5%), blanket (25.4%), and quilt (11.8%) or just in towels without any external source to provide warmth. Facility of oxygen therapy was available to only those babies who were brought in ambulances. A secure intravenous access was almost always lacking.

## INDICATIONS OF TRANSPORT

Infants requiring advance medical and/or nursing care exceeding what is available in their current settings will need transfer to a higher health facility. Reasons for transferring infants are: no appropriate local neonatal facilities; unavailability of cot; insufficient appropriate nursing or medical staff—for example, pediatric surgeons, cardiologists, unexpected delivery, and transfers back to local facility (reverse transport). The broad indications for which neonatal transport should be considered are given in **Box 1**.

## TYPES OF TRANSPORT

There is widespread agreement that neonates should have access to facilities appropriate to their care needs. Neonatal transfers can be categorized as follows:

- Intrahospital transport (including delivery suites, theaters).
- To facilitate specialist management of the neonate (movement to a regional center for cardiac, neurological, renal or surgical opinion).

### BOX 1 Indications for transport

- Very low birth weight infants especially below 1,250 g
- Prematurity: Gestational age < 32 weeks
- Respiratory distress or apnea
  - Requiring supplemental Oxygen or mechanical ventilation
- Cyanosis persisting despite oxygen therapy
- Hypoxic ischemic encephalopathy
  - Requiring intubation and assisted ventilation
  - Seizures
  - Multiorgan involvement
- Sepsis with signs of systemic infection
- Jaundice with potential for exchange transfusion
- Active bleeding from any site
- Infant of diabetic mother or hypoglycemia unresponsive to recommended treatment
- Surgical conditions
- Congenital heart disease (antenatal diagnosis or suspected)
- Heart failure or arrhythmia
- Suspected metabolic disorder
- Severe electrolytes abnormalities
- Infants requiring special diagnostic and/or therapeutic service.

- Retrieval from a peripheral hospital for ongoing intensive care within a level 3 unit (when mothers deliver prematurely without warning).
- Returning infants to local neonatal units following care elsewhere (either locally or long distance)—reverse transport.

## MODE OF TRANSPORT

The mode of transport (ground, air) should be determined by the transferring institution in consultation with the referral hospital. The thumb rule is to use *the safest and fastest means of transport that is available*. The vehicle used would depend on the local terrain, condition of the neonate, distance to be traveled, safety and cost. The transport vehicle should be compatible with weather and traffic conditions. Ground transport is useful for distances of 100–120 km, beyond which an aircraft is desirable. However, in places like India where proper ground transport is rarely available, air transport is utopian.

## ORGANIZATION OF TRANSPORT

### Pretransport Stabilization

Prior stabilization and adequate care during transport results in decreased risk of hypothermia, hypoglycemia, poor perfusion and mortality. Available models for pretransport stabilization and care during transport are:

- **STABLE:** Sugar, Temperature, Artificial breathing, Blood pressure, Laboratory work, Emotional support.
- **SAFER:** Sugar, Arterial circulatory support, Family support, Environment, Respiratory support.
- **TOPS:** Temperature, Oxygenation (Airway and Breathing), Perfusion, Sugar.

The following scheme may be followed for stabilization of neonates prior to transport:

### Assessment

Assess the baby and depending on facilities available check for temperature, airway, breathing, circulation and sugar. Identify special needs and circumstances that require additional intervention.

### Temperature

Assess temperature and consider the support required for transfer. Correct hypothermia if present before transport with radiant warmer at stabilization unit or referring center.

### Airway and Breathing

Make sure the airway is patent and secure. Assess airway for presence of any secretions (suction if present) and position of neck (place shoulder roll). Decision for need of intubation should be taken beforehand and a lower threshold for intubation should be used to minimize the need to intervene in transit. If the infant is unstable, has a rising oxygen requirement, has recurrent apnea/recurrent seizure, is on prostaglandin infusion due to duct dependent congenital heart disease, is extremely premature; then intubation and respiratory support is highly likely to be required. If already intubated, the endotracheal tube (ETT) must be correctly positioned and secured. Adequate respiratory support must be given. Surfactant should be administered if indicated.

### Circulation

Stabilize blood pressure, correct perfusion and severe acidosis. Document heart rate, BP, capillary refill time (CRT) and urine output in last 6 hours. Check what fluids baby is getting and assess for the need of fluid bolus and inotropes; adjust infusion of inotropes as per need. Arterial access should be considered in

infants who require repeated blood gas analysis or accurate blood pressure measurement. As portable hand-held arterial blood gas (ABG) machines are usually not used during transport in our country, so it may be acceptable to delay putting an arterial line until reaching the referral center.

### Sugar

Measure and stabilize blood glucose. Secure intravenous access and check the patency of IV cannula. Check sugar with glucometer; if blood glucose less than 40 mg/dL, give 2 mL/kg of 10% dextrose through intravenous line followed by continuous dextrose infusion at the rate of 6–8 mg/kg/min.

### Laboratory Work-up

Check and document all investigations and medications.

### Infection

If sepsis is suspected, give one dose of antibiotics.

### Transport Personnel

Trained transport team capable of monitoring and providing care is ideal. Trained nurse, paramedic or physician at the referring hospital is another alternative. Accredited social health activists from community or basic health facility are also involved in neonatal transfers.

### Equipment

A fully equipped neonatal transport ambulance should be used for transport. Raise the environmental temperature of the vehicle if possible. Ensure doors of vehicle are closed. Ensure doors of transport incubator are closed. If possible improve general comfort for the infant, use mattress that can absorb vibration and avoid sudden acceleration and deceleration of the vehicle.

### Parents' Information and Wishes

Discuss plans with parents and take informed consent. Discuss the condition of the baby and provide emotional support.

### Communication

Ensure the team at the referral unit will have all the necessary information to advance the care of the baby. Ascertain availability of bed, personnel and equipment at the arriving unit.

## Care During Transport

### Temperature Maintenance

Use a transport incubator. Transwarmer mattress is another effective option to keep infants warm. Innovative techniques like Embrace incorporates a phase change material to rapidly stabilize the temperature of an infant suffering from hypothermia. It is inexpensive and costs less than 1% of the cost of a standard incubator, reusable (50 times) and can be used while the baby is held in the mother's arms or during transport. Plastic wraps or bags have been shown to be low cost and effective method for neonatal transport. In resource limited conditions kangaroo mother care (KMC) is an important alternative method, when transport incubators are not available.

### Airway and Breathing

Keep neck of the baby in slight extension position; if airway is unstable, it is better to intubate and transport.

### Circulation

Assess perfusion for warm peripheries, capillary refill time of  $\leq 3$  sec, tone and activity, and blood pressure. Syringe infusion pumps are required to use inotropes with accuracy.

### Check Oxygenation

Continuous pulse oximeter monitoring is preferable; observe for central cyanosis; if possible perform blood gas analysis before and during transfer.

### Communication

Inform about baby's condition and vitals during transport so that adequate manpower and resources are kept ready at the referral unit.

## KEY COMPONENTS OF A TRANSPORT SYSTEM

In India, neonatal health-care delivery and transport systems are unregulated, patchy and not standardized. There is a need for development of Neonatal Transport Systems across the country with at least minimum standards. The key components of a transport system are discussed below:

### Human Resource

An organised neonatal transport service should consist of a *transport team*. A physician with specialty training in neonatology or equivalent expertise should be the *leader* of such a team. Most transport teams in western countries have a neonatal-trained nurse. Other programs use anesthetists, respiratory therapists, paramedics or a combination of these three disciplines. Trained nurses or paramedics for transport services are not available in India. Most units involved in organized neonatal transport utilize the services of residents and fellows working in neonatology for this purpose.

### Vehicle and Equipment

An ideal design of the vehicle and equipment for transport should have consideration of weight, fixation, power and gas requirements.

#### Transport Vehicle

The ambulance used for neonatal transport should, at a minimum, meet the requirements for a basic life support ambulance and must provide:

- Secure fixation of the transport incubator to the cot rails and fastening of other equipment (e.g., oxygen and air tanks, monitoring equipment).
- Independent power source to supplement equipment batteries to guarantee uninterrupted operation of the incubator and other monitoring and supportive equipment.
- Necessary adapters to access the ambulance power source should be readily available.
- Suction apparatus.
- Minimum two seats for transport staff.

#### Incubator Position

Offside mounting of incubator as compared to transverse mounting is quick and easy to load and enables more staff to be seated by the side with clear vision of the baby. Offside mounting is better fixed to the ambulance and provides more straightforward access for re-intubation if needed.

#### Fixation of Equipment

All equipment such as transport incubator, monitors, cylinders, infusion pumps etc. should be secured well enough to withstand sufficient force (10G force in five directions forward, rearward, left, right and vertical) in the event of sudden acceleration or deceleration.

### Speed of Vehicle

Our national guidelines state that speed of the ambulance should not be more than 15–20 km/hour over the posted speed limit.

### Equipment

The transportation of neonates requires several equipment (**Box 2**). These includes power back up, additional air and oxygen cylinders, neonatal ventilators. Some of the commercially available transport systems have ventilators that are integral to the incubator system (examples-Air-Shields Globetrotter TI500, Draeger Medical) or standalone systems (Pneupac® babyPAC™, Smiths Medical). These systems are now capable of functioning well at the full range of rates and inspiratory times required for neonatal practice.

- *Transport incubators* Some of the available transport incubator systems which provide adequate temperature control even in extreme conditions are (Airborne 750i, GE Health-care; Air Shields Globetrotter TI 500, Draeger Medical). A new solution to assist warming during transport is the use of phase-change gel mattresses which very effectively warm infants through release of latent heat of crystallization. It is important to secure the neonate inside the incubator. Neonatal harnesses are now commercially available (Neo-restraint, Paraid Medical) which consists of a series of foam wedges and straps, than can be adjusted to the position and size of the infant within the transport incubator.
- *Syringe infusion pumps* For neonatal transport, syringe infusion pumps are probably the best suited to deliver both maintenance fluids and drug infusions. Most pumps work on 240V power source and many work with an internal rechargeable battery that last for 4 hours.
- *Monitors* A multiparameter monitor is preferable. However, a lightweight portable pulse-oximeter is a good alternative. Pulse oximeters and monitors which use massimo technology would minimize or eliminate motion artefacts.

### Communication and Family Support

The family must be communicated in detail about the following aspects:

- Nature and severity of illness and the need for transport.
- Facilities available at referral hospital including infrastructure, details of key personnel.
- Type and mode of transport and time needed to reach the referral hospital.
- Names and contact numbers of key personnel at referral hospital.
- Possible need for emergency procedures during transport.
- The availability of bed should be asked before starting transport and referred hospital should be informed in advance.

The referring institute/physician has the responsibility to document and communicate to the transport team and the receiving institute (**Fig. 1**).

- Patient demographic details (name, age, sex, gestational age and weight, place and name of referring hospital)
- Reason for transfer
- Detail perinatal history, labor and delivery, neonatal resuscitation
- Current patient status, therapy and laboratory data (e.g., CBC, blood sugar)
- Potential for deterioration and need for advance therapy like mechanical ventilation and exchange transfusion or diagnostic evaluation
- Referral note with provisional diagnosis and treatment given so far
- Consent form from parents.

**BOX 2 Equipment required for neonatal transport***Thermal support equipment and supplies:*

- Transport incubator
- Thermometer and/or temperature monitor and probes
- Plastic wrap, insulating blankets, heat shield

*Respiratory support equipment:*

- Oxygen and air cylinders with appropriate indicators of in-line pressure and gas content
- Flow meters, oxygen tubing and adapters
- Oxygen hood, neonatal size masks and cannula
- Oxygen analyzer, pulse oximeter
- Neonatal positive pressure bags
- Continuous positive airway apparatus: nasal prongs, endotracheal tube
- Mechanical ventilator with back up circuit
- Endotracheal tubes: 2.5, 3.0, 3.5, 4.0 mm
- Laryngoscope with size 00, 0 and 1 blades
- Laryngoscope batteries and extralamps
- Endotracheal tube holders and tape to secure ET tube

*Suction equipment*

- Mucus suction trap, suction catheters (5, 6, 8, 10, 12 F)
- Regulated suction with gauge limiting < 100 mm Hg
- Feeding tube (8 Fr) and 20 mL syringe for orogastric decompression
- Sterile gloves, sterile water for irrigation

*Monitoring equipment*

- Stethoscope, cardiac monitor, pulse oximeter
- Glucometer for blood sugar evaluation

*Infusion equipment*

- Intravenous catheters (24, 26 gauge)
- Syringes (2, 5, 10, 20, 50 mL)
- Splint, transparent dressings or micropore
- Three way stopcocks, IV chamber sets/microdrip sets
- Intravenous administration tubing compatible with infusion pump

*Medications*

- Calcium gluconate 10%
- Epinephrine (1:10000) prefilled syringes, sodium bicarbonate
- Dopamine, dobutamine, morphine, midazolam
- Normal saline, phenobarbitone, surfactant.

The transport team should communicate to the receiving institute the condition of the baby and the probable time at which they are likely to arrive so that they can be received preferably in the emergency area and shifted to NICU. Once the baby is received and stabilized in the receiving unit the transport team should communicate with the referring unit about the condition of the baby.

**SPECIAL CONSIDERATION****Respiratory Distress Syndrome**

Oxygenation, perfusion should be maintained throughout the transport. Depending on degree of respiratory distress, appropriate ventilator support may be provided with oxygen, continuous positive airway pressure (CPAP) or mechanical ventilation. Babies requiring mild to moderate respiratory distress may be transported on nasopharyngeal CPAP as binasal prongs are likely to get dislodged during transport. The endotracheal tube should be firmly secured and position ensured clinically before embarking on transporting a baby with severe respiratory distress on mechanical ventilator. Infants who need high frequency ventilation in transit currently present a problem, as there is no oscillatory ventilation option on commonly available transport ventilators. Clinical teams will usually have to convert oscillation to standard ventilation for transfer, and there is anecdotal experience of using inhaled nitric oxide (iNO) to support this conversion and make transfer possible in very unstable infants.

**Figure 1** Sample referral note and documentation sheet

**Air Leak Syndromes**

Even mild pneumothoraces may worsen during transport. Hence, it is advisable to drain the pneumothorax adequately and preferably keep a chest tube in place before departure.

**Esophageal Atresia**

A continuous suction with the help of two catheters (one attached to suction and the other left open to air—*repolage tube*) should be done during transport in babies with esophageal atresia to prevent pulmonary aspiration.

**Meningomyelocele**

The exposed swelling on the back should be covered with gauze piece soaked in normal saline and baby should lie on the side or prone but not back during transport.

**Abdominal Wall Defects**

Due to increased exposed surface area and the fluid exudation causing evaporation, maintenance of fluid electrolyte balance is very important. The bowel/membranes should be wrapped with a clean plastic film without compressing, twisting and kinking the bowel. Gastric decompression is essential with a size 6 or 8 Fr tube should be done.

**Consideration During Air Transport****High Altitude**

The barometric pressure in a standard airline carrier is 565 mm Hg as compared to 760 mm Hg at sea level resulting in reduction of partial pressure of oxygen. Every effort therefore must be made to maximize oxygen delivery in hypoxic infants. As air expands at high altitude and even benign air leaks at sea level

are likely to become significant, they should be drained before embarking on air transport. Need for supplemental oxygen may increase by 20–30% during air transport.

### Take-off and Landing

Rapid acceleration during take-off and rapid deceleration on landing may cause a sudden change in cerebral perfusion. There is provisional evidence that premature infants undergoing transfer may have a higher incidence of intraventricular bleeding.

### Temperature

There is a temperature drop of 2°C for every 300 m of altitude, and in unheated military helicopters this may put high demands on the transport incubator system. A reliable method of measuring infant temperature during transport must be used. The incubator used for air transport must always have fully charged batteries at the beginning of a transfer. DC power cables suitable for both the aircraft and the ambulance should be taken.

### Noise and Vibration

Vibration is not usually detrimental to the infant, but can dislodge lines and tubes and adversely effect monitoring equipment. Consideration should be given to equipment specifically designed to minimize the effect of movement artefact such as pulse oximetry using Masimo or Oxismart technology. During transport all lines should be secure and visible, particularly arterial lines, to allow observation without the need to open the incubator. Visual rather than audio alarms should be used where possible. The long-term effects of exposure of the newborn infant to excessive sound remain unclear.

## COMPLICATIONS OF TRANSPORT

- Hyperventilation during manual ventilation may cause respiratory alkalosis, cardiac dysrhythmias and hypotension.
- Loss of positive end-expiratory pressure (PEEP)/CPAP may result in hypoxemia.
- Position changes may result in hypotension, hypercarbia and hypoxemia which may increase the chances of intraventricular hemorrhage.
- Equipment failure.
- Inadvertent disconnection of intravenous drugs.
- Movements may cause disconnection from ventilatory support and respiratory compromise.
- Movements may result in accidental extubation.
- Movements may result in accidental removal of vascular access and bleeding.
- Loss of oxygen supply may lead to hypoxemia.

## MEDICOLEGAL ISSUES

Most medicolegal problems are a result of poor communication and provision of inadequate information. The condition of baby, risks involved during transport and financial implications of transport and treatment at the referral center should be discussed with family and documented in the case record. If baby dies during transport:

- The ambulance should be stopped and cardiopulmonary resuscitation should be performed as per neonatal resuscitation program guidelines.
- If baby dies on the way, he/she should be first taken to the higher health facility.
- Casualty admission should be done. Parents should be explained and death certificate made by the medical personnel of higher health-care facility.

- It is the responsibility of transporting team to make death certificate of baby.

## QUALITY MANAGEMENT PROGRAM

Quality assurance is now an integral part of patient care in medicine. In addition to patient care issues, a quality management program should assess all aspects of transport program. This includes management of vehicles, operational and safety issues, training of manpower, maintenance of licensure and establishment of patient care guidelines. The institution providing transport services should have predefined and prospective quality indicators and should follow standards of operation and regional standards of care. Thresholds of compliance for acceptable outcome should be decided and an annual review should be made of the quality assurance process to improve transport services and overall neonatal outcome.

### IN A NUTSHELL

1. Neonatal transport programs require appropriate referral systems, management structures and trained transport personnel. They need to utilize transport equipment, address transport logistics and have a quality improvement program.
2. Infants requiring advance medical and/or nursing care exceeding what is available in their current settings will need transfer to a higher health facility.
3. Prior stabilization and adequate care during transport results in decreased risk of hypoglycemia, acidosis and mortality.
4. The key components of neonatal transport are human resources, vehicles and equipment, communication, family support and documentation.
5. In India, neonatal health-care delivery and transport systems are unregulated, patchy and not standardized. There is a need for development of Neonatal Transport Systems across the country with at least minimum standards.

## Chapter 14.14

# Follow-Up of the High-Risk Neonate

Shuchita Gupta

The low- and middle-income countries (LMICs) have huge burden of perinatal illnesses like prematurity, intrauterine growth retardation, neonatal encephalopathy, sepsis/meningitis, jaundice and congenital defects. These insults not only result in a high neonatal mortality, but also carry a higher risk of postdischarge mortality and morbidities, including long-term sequelae like poor neurodevelopment and adverse health outcomes like hypertension and cardiovascular disease.

The decline in global neonatal mortality rate by 28% (from 33.2 deaths to 23.9 deaths per 1,000 live births) between 1990 and 2009, suggests that increasing number of infants with perinatal risk factors are now beginning to survive. This is likely to result in increased postdischarge mortality, morbidities requiring hospitalization, and long-term illnesses and disability requiring frequent health-care services. This will not only affect the quality of life of the surviving infants, but also add significantly to the family's socioeconomic burden.

To ensure continuum of care and prevent postneonatal mortality and morbidity, it is mandatory to have a dedicated follow-up program linked to the neonatal units. Monitoring postdischarge outcomes would not only help in early identification and management of problems while still amenable to prevention and/or treatment, but also to counsel and prognosticate parents with respect to specific conditions. Standardized documentation of follow-up data would also allow ascertainment of association between various perinatal risk factors and outcomes and identify previously unidentified problems.

## ESTABLISHING FOLLOW-UP PROGRAM

### Setting

It is imperative that a follow-up program for the high-risk infants be an integral part of the neonatal services. There should be a dedicated clinic along with a multidisciplinary team of trained, skilled and experienced personnel. In small hospitals, if a multidisciplinary team is not available, appropriate referral services should be identified in the region where such infants may be referred for formal evaluation and management.

### Personnel and their Roles

The follow-up team should include a pediatrician/neonatologist, who has the overall responsibility of the follow-up program and he should have adequate knowledge and training in follow-up of high-risk infants. It is his duty to assess the child with regard to growth and nutrition, provide medical management for any continuing or intermittent morbidities, ensure timely immunization, screen for development and neurological intactness and refer for appropriate services as appropriate/as required. It is also his duty to coordinate care, regularly assess child's progress and counsel the family. Other important members include:

- *Clinical psychologist* trained in doing pediatric assessments to perform formal developmental evaluation.
- *Physiotherapist* to provide training exercises to infants with tone abnormalities.
- *Occupational therapist* to work at improving neuromotor coordination and perceptual skills in the infants and train

them in activities of daily living, like feeding, bathing and dressing, which require fine motor function and oro-motor coordination.

- *Special educator* is required to promote developmental potential through an understanding of the special needs of differently-abled children. He/she focuses on behavior, cognitive, social, language, emotional and self-care skills and academic development to promote holistic learning in such children. In resource restricted settings, a person trained in transdisciplinary work may also be considered to provide services expected of the therapists and the special educator combined.
- *Medical social worker* is a desirable member of the follow-up team. This person would assess the family conditions, home environment and parental perspectives, priorities and expectations, which are important to know in order to provide appropriate, individualized care to any infant. A medical social worker may also help families with regard to social and socioeconomic issues and help in rehabilitation of the differently-abled children.
- *Other specialists* like ophthalmologist, audiologist and speech therapist, nutritionist, and pediatric neurologist and geneticists are consulted as per the needs of an individual child.

It might not be possible in all health-care facilities to have a complete team of specialists as outlined above. It is therefore important to have a linkup with specialized services where appropriate referrals may be sought when required.

#### Follow-up Team

Essential members of follow-up team:

- Pediatrician/neonatologist, trained in follow-up of high-risk infants
- Clinical psychologist (trained and experienced in pediatrics)
- Physiotherapist, occupational therapist and special educator (trained and experienced in pediatrics); or a person trained in transdisciplinary work
- Medical social worker.

For specialized referrals in selected cases:

- Ophthalmologist, audiologist and speech therapist, nutritionist, pediatric neurologist and geneticist.

## DISCHARGE PLANNING

Discharge planning should begin early during the infant's hospitalization to ensure successful transition to home care. The following criteria should be fulfilled before discharging any high-risk infant from the hospital:

- Free of any significant medical/surgical illness
- Should not be on injectable drugs (antibiotics/other)
- Should be on full enteral feeds (either direct breastfeeding or by spoon/cup)
- Appropriate micronutrient/multivitamin supplementation has been started, vaccination has been initiated based on postnatal age and parents are confident to take care of the infant at home
- For very low birth weight (VLBW) infants, in addition to above, the following are essential:
  - Should ideally be off caffeine/theophylline and apnea free for at least 5 days prior to discharge
  - Be able to maintain body temperature in an open crib
  - Have had stable weight gain for three consecutive days
  - The discharge weight should be around 1,400 g.

It might be necessary in some resource limited settings to individualize some of the above criteria. In such cases, it would be important to call such infants 3–7 days postdischarge to ensure successful transition of the infant to home care.

*Discharge Summary*

It is very important to provide a detailed discharge summary to all high-risk neonates at discharge which should include details of the perinatal course, investigations, important advice including oral medications, danger signs and follow-up schedule with venue, dates and timing (including dates/time/venue for special visits like neuroimaging, ROP screening, ABR, etc.).

**INITIATING FOLLOW-UP**

A few components of care that have important implications for follow-up, but need to be initiated within the neonatal intensive care unit are as follows:

**Neuroimaging**

Routine screening cranial ultrasonography (CUS) should be performed on all infants less than 30 weeks gestation once between 7 days and 14 days of age and should ideally be repeated between 36 weeks and 40 weeks' postmenstrual age (PMA). This helps to detect lesions such as intraventricular hemorrhage (IVH), periventricular leukomalacia (PVL) and ventriculomegaly, which are all associated with adverse neurodevelopmental outcome. A routine MRI of all VLBW preterm infants is not presently recommended, even if they have abnormal findings on CUS.

*Abnormalities on Cranial Sonogram*

- Twelve to fifty-one percent of infants with birth weight less than 1,500 g and/or gestation less than 33 weeks have CUS abnormalities. However, major abnormalities such as grades 3 and 4 IVH, cystic PVL and ventriculomegaly, which might alter treatment or provide prognostic information, are more common (20–25%) in infants with gestational age less than 30 weeks.
- Grades 3 and 4 IVH, cystic PVL, and moderate to severe ventriculomegaly on CUS have all been shown to be significantly associated with cerebral palsy at 2–9 years of age in VLBW preterm infants, with almost a tenfold elevation in the risk of adverse outcome.

For term infants, neuroimaging is indicated only if the infant has encephalopathy with a history of birth trauma, low hematocrit, or coagulopathy. In such case, a noncontrast CT should be done first to detect any hemorrhagic lesions. If CT findings are inconclusive, MRI should be performed between 2 days and 8 days to assess the location and extent of injury, wherein the pattern of injury may provide diagnostic and prognostic information.

**Retinopathy of Prematurity Screening**

The first retinopathy of prematurity (ROP) screening for infants less than 32 weeks or 1,500 g and other preterm neonates more than and equal to 32 weeks or birth weight more than and equal to 1,500 g but with risk factors like need of cardiorespiratory support, prolonged oxygen therapy/ventilation, anemia requiring blood transfusion, sepsis and apnea, etc. should be done at 32 weeks postmenstrual age or 1 month of postnatal age, whichever is earlier. If screening detects ROP not requiring treatment, follow-up should be planned according to the location and stage of ROP, and should continue till 40–44 weeks PMA, or till the retinal vessels have matured.

**Metabolic Screening**

Neonatal screening for congenital hypothyroidism, congenital adrenal hyperplasia and glucose-6-phosphate dehydrogenase deficiency is presently being recommended in India, as the screening and treatment is likely to be cost-efficient when compared to the cost of the permanent mental subnormality that would occur in these children if diagnosed late. In view of the

limited facilities available at most centers for routine metabolic screening, a universal screening might not be feasible at present.

**Hearing Screening**

Hearing screening should be performed for all high-risk infants prior to discharge, taking care to do the first screen for premature infants not before 34 weeks PMA, as this might increase the false-positive rates. Either otoacoustic emissions (OAEs) or automated auditory brainstem response (AABR) may be used, but it is important to carry out a two-step screening (two-step AABR or OAE followed by AABR) as this has shown to decrease false-positive results. An AABR should ideally be incorporated for screening of high-risk infants as the risk of auditory neuropathy is high.

**Follow-up Plan for Unresolved Problems**

Management plan for unresolved medical/surgical problems should be formulated prior to discharge in collaboration with the supporting units (e.g., pediatric surgery team for gastrostomy/inguinal hernia, ear, nose and throat team for tracheostomy, cardiology team for congenital heart disease, genetics team for genetic/chromosomal abnormality, etc.).

**Neurological Assessment**

A baseline neurological examination should be done in all high-risk infants prior to discharge, as it has now been shown to be an important predictor for later neurodevelopment.

In general, the predictive ability of isolated neurological signs in the neonatal period is not considered to be very good. However, on comparing a large population of predominantly term infants who later developed cerebral palsy to those who did not, certain neurological abnormalities were found to be particularly valuable predictors for later neurodevelopment (**Table 1**). A combination of neurological abnormalities increases the predictive ability, and clear relationship has been demonstrated between the severity of abnormality on neurological examination at discharge and motor abnormalities at 1–5 years of age (**Table 2**).

**Table 1** Neurological abnormalities: Predictors of later cerebral palsy

Neurological abnormality	Risk of cerebral palsy
Tone abnormality of limb, neck, trunk	12–15 times higher
Diminished activity or cry for more than the first day of life	19–21 times higher
Weak or absent sucking during exam (~48 hours of life)	14 times higher
Need for gavage/tube feeds	16–22 times higher

**Table 2** Abnormal neonatal neurodevelopmental examination and later neuromotor outcome

Grading of abnormality on neurological examination at discharge	Outcome at 1–5 years of age		
	Cerebral palsy	Minor neuromotor dysfunction	Normal motor outcome
None (n = 30)	3%	3%	94%
Subtle (n = 45)	7%	13%	80%
Mild (n = 50)	7%	18%	74%
Definite (n = 57)	33%	26%	42%
Marked (n = 28)	50%	29%	21%

Source: Allen MC, Capute AJ. Neonatal neurodevelopmental examination as a predictor of neuromotor outcome in premature infants. *Pediatrics*. 1989;83:498–506.

There are a variety of neonatal neurological examination tools that have been used across the world with variable predictive abilities for later adverse neurodevelopmental outcomes. The most commonly used tools that have been widely used and validated include the Amiel-Tison neurological examination at term (focuses primarily on neuromotor component including tone and primitive reflexes), Brazelton neurobehavioral examination (focuses on behavior), the Prechtl's assessment (focuses on the observation of general movements), and the Dubowitz examination (encompasses various aspects of neurological function such as behavioral states, tone, primitive reflexes, motility and some aspects of behavior). There is no consensus on which of these tools to be used. A simplified proforma for routine clinical use is depicted at **Figure 1**.

## FOLLOW-UP SCHEDULE

### Frequency of Follow-up

The periodicity and schedule of follow-up of high-risk infants is guided by several factors. These include developmental attainments at a given age, availability and applicability of suitable test instruments at specific ages, need for additional services like immunization, complementary feeding advice, other special services, etc. **Box 1** outlines a follow-up schedule that can be used by most facilities and also adapted and modified to the needs of each setting. But, some of the periods of assessment are critical and are summarized below:

#### 9–12 Months of Age

Most medical issues have been taken care of by 9–12 months of corrected age (CA), and environmental factors are also less influential on performance. At this age, many issues involving motor skills development can be reliably identified. Some neurologic abnormalities that are identified in the first year of life are transient and improve, whereas other may worsen over time. The child's visual and hearing abilities, and emerging early communication skills, like social and nonverbal communication (including vocalizations and gestures), may also be assessed at this age. These may provide clues to early diagnosis of autism (lack of eye contact, orienting to name being called, or pointing).

#### 15–18 Months

Mild motor delays (that remained undetected at 9 month) and delays in communication and language development are often evident by 18 months of age. General formal development assessment in all domains (including gross and fine motor, cognition, receptive and expressive language), social-adaptive assessment as well as behavior and autism screening tools may be

administered at this age. Effective early intervention therapies for motor disorders, delayed language development and autism are also available at this stage.

#### 24–30 Months

By 2–2½ years of age, most motor, language, and cognitive delays may be identified with screening instruments, leading to evaluation of and intervention for those children with delayed development.

#### 5–6 Years

By this age, the preschool skills and school readiness may be assessed. By 6 years of age school achievement and intelligent quotient (IQ) can be assessed; and by 8 years, school performance may be assessed.

#### Calculating Corrected Age

- For any preterm infant less than 37 weeks of gestation, growth and development is assessed as per the CA at least till 2 years of CA.
- Calculate as follows:
  - *Postnatal age*: Age as calculated from the date of birth
  - *Corrected age (CA)*: Age as calculated from expected date of delivery (EDD)

Formula CA (in weeks) = (Postnatal or chronological age in weeks) – (40 – gestational age in weeks).

*Example*: B/o XYZ is born on 27th March, 2014 at gestation of 32 weeks (EDD: 22nd May, 2014), is brought for follow-up visit on 3rd July 2014. Then, the postnatal age of the child as on 3rd July, 2014 would be 14 weeks and CA would be 6 weeks.

*\*The terms postmenstrual or postconceptual age (though the two are slightly different) are frequently used to describe the age of a premature baby till term equivalent age/EDD, beyond which the term CA is used.*

## WHAT SHOULD BE DONE?

This section outlines the assessment that should be carried out during the follow-up visits. **Table 3** provides a checklist for the assessment during various follow-up visits.

### Assessment of Feeding

During each follow-up visit, it is important that feeding is assessed. Feeding should be assessed as per standard guidelines for age (i.e., exclusive breastfeeding for 6 months followed by complementary feeding). During each visit the health-care provider should also ensure compliance with micronutrient/vitamin supplements.

There are no standard guidelines on time of initiation of complementary food for preterm infants, and practices vary among experts. The decision should be guided by the developmental appropriateness of any individual infant, type of feeding being given and the growth trajectory of the infant.

### Growth Monitoring

For term normal birth weight infants, the postnatal growth may be monitored using World Health Organization-Multicenter Growth Reference Study (WHO-MGRS) growth curves, freely available and downloadable from the WHO website (<http://www.who.int/childgrowth/en/>). Monitoring postnatal growth among premature and/or low birth weight (LBW) infants remains a controversial issue with different postnatal charts being available, with their relative merits and demerits.

For term LBW infants, the WHO-MGRS charts may be used. However, it is important to consider here that the WHO-MGRS charts are primarily based on a sample of term, healthy breastfed

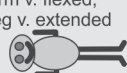

#### BOX 1 Follow-up schedule for various categories of high-risk infants

##### Very preterm infants (< 32 weeks or < 1,500 g)

- After 3–7 days of discharge to check if the baby has adjusted well in the home environment
- Every 2 weeks until a body weight of 3 kg (6, 10 and 14 weeks—immunization visits to be covered during these visits)
- At 3, 6, 9, 12, 15 and 18 months of corrected age and then every 6 months
- More visits if required

##### Infants with other conditions

- 2 weeks after discharge
- At 6, 10, 14 weeks of age
- At 6, 9, 12, 15 and 18 months of corrected/postnatal age, as applicable; and then every 6 months
- More visits if required.

	Abnormal	Optimal	Abnormal/deviant	Comments
<b>Posture</b> Baby lying supine, look at position of legs mainly but also note arms. May change drawing	Arms and legs extended 	Leg well-flexed but not adducted 	Opisthotonos or arm v. flexed, leg v. extended 	
<b>Arm traction</b> Hold wrist and pull upwards, note flexion at arm and resistance while shoulder lifts off table	Arms remain straight—no resistance 	Arms flex and remain flexed as 	Arms remain flexed when body lifts up 	
<b>Leg traction</b> Hold ankle, pull leg upwards. Look at flexion and resistance as bottom pulled up	Legs straight—no resistance 	Knee flexes—remains flexed when bottom lifts up 	Flexion stays when back+bottom lifts up 	
<b>Head control (1) (extensor tone)</b> Infant sitting upright, encircle chest with both hands holding shoulders. Let head drop forward	No attempt to raise head 	Raises head: remains vertical, wobbles 		
<b>Head control (2) (flexor tone)</b> Infant sitting upright, encircle chest with both hands holding shoulders. Let head drop forward	No attempt or raise head 	Raises head: remains vertical, wobbles 		
<b>Head lag</b> Pull infant to sit by both wrists and support head slightly	Head drops back	Lifts head in line with body 		
<b>Ventral suspension</b> Hold infant horizontally under the abdomen. Look at back, arm and limb position. It looks different—DRAW	Back curved, head and limbshang straight 	Back straight, head in line or above body 		
<b>Body movements</b> Observe during the examination when the infant is awake and quiet	Absent infrequent	Mainly smooth alternating	Cramped, athetoid, jerky, or other abnormal movements, describe	
<b>Tremors and startles</b>		Only occasional	Tremolous always many startles	
<b>MORO</b> Put infant in position shown in diagram. Bring head forward and suddenly let it go back slightly 	No response; full abduction or the arm, extension at the elbow; no adduction 	Full abduction, followed by adduction 	• Minimal adduction or abduction • Difficult to elicit	
<b>Auditory orientation</b> Ability to respond to rattle. Rattle 5 inch/from ear	No response	Brightens, turns to stimuli either side		
<b>Visual orientation</b> Able to track red ball or target	No focusing: tracking $\leq 60$	Good horizontal and vertical tracking		
<b>Alertness</b> Response to visual stimulation	When awake variable response to orientation	Alertness sustained, may use stimulus to come to alert state		
<b>Abnormal signs</b>	<b>Facial palsy</b> Y N	<b>Abnormal eye movements</b> Y N	<b>Sunset sign</b> Y N	<b>Fisted hand</b> Y N
				<b>Clonus</b> Y N

NB: Infants with 2 or items in shaded areas need to be reassessed.

**Figure 1** Simplified proforma for neurological examination of the newborn infant at discharge  
Source: Reproduced with permission. From: Mercuri E, et al. The neurological examination of the newborn baby. Early Human Dev 2005;81:947-56. ©Elsevier.

**How to use:** The items in the first column are always abnormal in a full-term infant. Infants with more than and equal to two items in the first column or showing more than and equal to one of the abnormal signs listed at the end of the proforma should be reassessed. If the abnormal signs persist, a more detailed assessment is required.

**Table 3** Checklist of assessments to be done at various follow-up visits

Assessment	Corrected or postnatal age, as applicable								
	3 months	6 months	9 months	12 months	18 months	24 months	3 years	6 years	8 years
Nutrition and growth	✓	✓	✓	✓	✓	✓	✓	✓	✓
Medical examination and management as required	✓	✓	✓	✓	✓	✓	✓	✓	✓
Immunization	As per postnatal age; decide schedule based on vaccines being given								
Hearing (ABR)	✓	α	Clinical screening at each visit						
Language			✓		✓	α			
Vision			✓	α	α				
Developmental screening	✓	✓	✓	✓	✓	✓	✓	✓	✓
Formal developmental assessment	✓				✓		✓		
Autism and behavior screening					✓	α	α	✓	
Intelligence (IQ)								✓	✓
ADHD/learning disability/others								✓	✓

α If previous test abnormal

Abbreviations: ABR, auditory brainstem response; ADHD, attention deficit hyperactivity disorder.

infants, with only a small proportion of term LBW infants. Therefore, the growth of LBW infants as plotted on the WHO-MGRS charts may not accurately reflect their optimal growth trajectory. It would also be difficult to comment upon the catch up growth, if any, among these infants.

For premature infants, especially those less than 1,500 g at birth, there are various charts available for monitoring postnatal growth—Ehrenkranz's charts, Niklasson's charts and Fenton's charts. It may at present be best to use the latest Fenton charts till preterm infants attain 40 weeks postconceptional age and the WHO-MGRS chart thereafter.

#### Use of Growth Charts in LBW Babies

- Use WHO-MGRS growth charts for term infants and Fenton's growth charts for preterm infants (these merge with WHO-MGRS curves at 50 weeks PMA).
- Alternately, but less preferable, is to be guided by the absolute weight gain till term age and then used WHO-MGRS growth curves.

Remember that the growth of LBW (premature/intrauterine growth restriction) might continue to remain at less than third centile on WHO-MGRS growth curves. If these infants continue to maintain their trajectory and show some catch up growth (using weight for length charts), it might be considered to be adequate.

### Medical Examination and Management of Ongoing/Intermittent Morbidities

At each follow-up visit, a detailed evaluation and management of the infant should be done in accordance with the perinatal history/insults. These may relate to prolonged jaundice due to any cause, recurrent exacerbations of respiratory insufficiency in a child with chronic lung disease, gastroesophageal reflux or other feeding difficulties or inadequate weight gain in a preterm infant, anemia in a baby with Rh immunization, cardiac failure in a baby with congenital heart disease, diagnostic evaluation and intermittent illnesses in a baby born to HIV-positive mother, etc.

### Immunization

The immunization should be done as per the chronological/postnatal age of the child. The national immunization schedule for any country should be taken as the reference for the mandatory

vaccines required to be given to any child. The advice on optional vaccines may be given depending upon the epidemiology of the disease in the particular geographical region and vaccine efficacy and safety. A detailed guideline on the same is beyond the scope of the present chapter and the reader is advised to refer to the section on immunization in this book.

### Hearing Assessment

For any infant who has failed a two-step hearing screening prior to discharge, it is important to ensure that the conventional auditory brainstem response is done by an audiologist during follow-up. Hearing aids, if required, should be fitted by 6 months of age to allow normal acquisition of language.

Infants who have passed a two-step neonatal hearing screening might still be at risk of permanent hearing loss. It is therefore important to track the infants' auditory behavior and communication milestones at each follow-up visit. If any concern arises with regard to the same, it is necessary to refer the infant to a pediatric otorhinolaryngologist for evaluation and further audiological assessment.

### Visual Assessment

Evaluation for vision should continue during all high-risk visits. All parents should be asked age appropriate questions related to visual behavior as detailed in **Table 4**. In children younger than 3 years or in any nonverbal child, vision is assessed by the child's ability to fix and follow objects. A failure to fixate on an object, maintain fixation, and then follow the object in different gaze positions indicates significant visual impairment.

*If poor fix and following is noted binocularly after 3 months of age, a significant bilateral eye or brain abnormality might be present and the child should be referred to a pediatric ophthalmologist or an eye care specialist trained in evaluating and treating pediatric patients.*

In addition, an external penlight evaluation of the lids, conjunctiva, sclera, cornea and iris should be done. Ocular alignment should be seen for any strabismus, pupils should be examined and red reflex test performed. This will help detect opacities in the visual axis, such as cataract and abnormalities of the back of the eye, such

**Table 4** Age-appropriate visual history

Age	Visual behavior
1st month	<i>Does the child</i> looks at the face of the person holding them?
2–3 months	<i>Does the child:</i> Follow moving object (till or past midline)? Look from one person/object to another? Look into the eyes of the person holding them?
4 months	<i>Does the child:</i> Show visual interest to near and distant objects? Responds to full range of colors?
6 months	<i>Does the child:</i> Enjoy looking at mirror? Show sustained visual interest at near and distant objects? Demonstrates hand-eye coordination? Maintains fixation at a stationary fixation on stationary object, even if another moving object is present?
7–12 months	<i>Does the child:</i> Notice small objects such as breadcrumbs? Recognize objects that are partially hidden? Scan eyes around the room to see what is happening?
18 months	<i>Does the child:</i> Point to objects or people using words <i>look</i> or <i>see</i> ? Look for and identify pictures in books?
24–36 months	<i>Does the child:</i> See small pictures well with both eyes? Show ability to arrange similar pictures in groups?

as retinoblastoma or retinal detachment. Presence of nystagmus should also be noted. All children who are found/suspected to have an ocular abnormality should be referred to an ophthalmologist trained in pediatric assessments.

### Neurological Examination

Neurological examination at discharge has been detailed in the previous section. It is important to repeat the neurological examination on follow-up as sequential assessments are more informative than isolated examinations.

Amiel-Tison neurological examination is most useful during follow-up assessments, as it is simple and precise, is based on a fixed set of observations and maneuvers, the results are scored according to the child's age (this is important because cerebral maturation modifies the results with age), and a single tool can be used from birth till 6 years of age.

The Amiel-Tison neurological examination incorporates the following:

- **Observation and interview with parents:** Parents are asked about any episodes of seizures, quality of alertness and attention and any symptoms of hyperexcitability. Child is also observed for alertness and attention and hyperexcitability.
- **Motor development milestones in first 2 years:** The age at acquisition of various developmental milestones is assessed and a delay/absence of the age appropriate milestones is noted.
- **Head growth and craniofacial examination:** Head circumference is evaluated as per the reference growth charts and interpreted in accordance with other growth parameters like length. Head growth profile during the first 2 years of life is also taken into account. Craniofacial examination incorporates examination of anterior fontanel, cranial sutures, shape of the skull and shape of palate.

- **Neurosensory examination:** It includes assessment of hearing, vision and ocular signs like fix and track, nystagmus, eye movements, and presence of strabismus and sunset sign.
- **Passive muscle tone:** The muscle tone at rest is evaluated through resistance to slow stretching/slow passive movements. The angles to be measured are detailed in **Table 5** and the techniques depicted in **Figures 2 to 5**. It is desirable to use a goniometer to measure the various angles as it gives a more reliable estimate. It is however important to note that the resistance to movement as felt by the examiner is equally important though it needs some experience before one may comment on normal/abnormal tone. Hypertonia and hypotonia imply that the range of passive movement is either too limited or too wide for age standards.

**Figure 2** Measuring the adductor angle using goniometer**Figure 3** Measuring popliteal angle

It is important to remember the following points while evaluating passive tone of a child:

- The reference values get modified at three monthly intervals over first 9 months and at less frequent intervals thereafter.
- There is a wide range of normalcy in relation to individual, familial and ethnic variations.
- A complete lack of resistance to stretching might be normal between 9 months and 18 months.
- One should distinguish *physiological hypotonia* from other conditions of congenital hypotonia where resistance to stretching will be very weak from the first few months of life.

**Figure 4** Measuring dorsiflexion angle

**Figure 5** Eliciting the scarf sign

**Table 5** Muscle tone norms (Amiel-Tison)

Age (months)	Adductor angle (Fig. 2)	Popliteal angle (Fig. 3)	Dorsiflexion angle (Fig. 4)	Scarf sign (Fig. 5)
0–3	40°–80°	80°–100°	60°–70°	Elbow does not cross midline
4–6	70°–110°	90°–120°	60°–70°	Elbow crosses midline
7–9	110°–140°	110°–160°	60°–70°	Elbow goes beyond axillary line
10–12	140°–160°	150°–170°	60°–70°	–

*At 40 weeks PMA, there is physiological hypertonia of flexor muscles in all four limbs with subsequent muscular relaxation in the cephalocaudal direction, linked to cerebral maturation. This results in a physiological hypotonia between 9 months and 18 months of age, which can vary in intensity. Later, between 2 years and 6 years of age, there is a slow and progressive increase in resistance to passive stretching, depending on extracerebral factors like muscle mass and strength of articular ligaments which are linked to the physical activity of the child.*

In addition to the above angles to evaluate the passive tone, passive extension and flexion of the body axis, hand and finger movements, and presence/absence of candle stick posture (shoulder girdle retraction due to shortening of trapezius) are also noted and right and left sides of the body are compared for asymmetry.

- **Motor activity:** This includes evaluation of facial expressions (normal, symmetric, varied), drooling, facial paralysis, fasciculations of tongue, spontaneous limb movements, any involuntary movements and dystonia.
- **Deep tendon, cutaneous and primitive reflexes:** The bicipital, patellar and plantar reflexes are assessed. The primitive reflexes, like Moro's, finger grasp, automatic walking and asymmetric tonic neck reflex (ATNR) are seen as they are indicators of subcortical cerebral function, and their persistence beyond 6 months of age is considered pathological. ATNR is particularly important reflex as it needs to be integrated before an infant may initiate midline activities and turning of body.
- **Postural reactions:** Postural reactions appear during the first year of life in response to rapid movements felt by the infant, and help in maintaining balance. Once they appear, they persist throughout life. Their absence after a particular age is considered pathological. The lateral propping reaction (extension of opposite arm when briskly pushed from the other side laterally at shoulder level); should be present by 9 months of age (*Note: this reaction is elicited only after a child*

can sit independently well). The parachute reflex (extension of both upper limbs on head being pushed forward in ventral suspension) should be present by 12 months of age.

- **Qualitative abnormalities in gross motor function and acquired deformities:** Abnormal signs like holding head behind axis, poorly maintained head control due to fatigue, failure to sit due to falling forward/backward, poorly maintained sitting position due to fatigue, excessive extension while standing and lower limb deformities like crossing of legs in extension or scissoring are noted, along with gait of the child.

## Developmental Screening and Assessment

For any infant during follow-up, developmental surveillance is required, which comprises a review of the perinatal risk factors, asking parents about any concerns with regard to development of their child, and eliciting a developmental history. For a high-risk infant, it is necessary that we go a step further and objectively screen them for age appropriate development using standardized developmental screening tests. This is important because these infants are at a higher risk of adverse neurodevelopmental outcomes, and need to be recognized early to be able to benefit through developmental interventions.

Developmental screening should be done using standardized tests at each high-risk visit as repeated and regular screening is more likely than a single screening to identify problems, especially in later developing skills such as language. Any child who fails the screening should be referred for a formal developmental assessment, along with complete medical evaluation. **Table 6** enlists the commonly available and used screening tests in India. The other screening tests available for different domains of development are Modified Checklist for Autism (M-CHAT), Vineland Social Maturity Scale and Vineland Adaptive Behavior Scales, and Child Behavioral Checklist-Language development scale (CBCL-LDS 1½).

**Table 6** Developmental screening tests commonly available in India

Test	Domains assessed	Age range	No. of items	Psychometric properties
Trivandrum development screening test (TDSC)	Gross motor, fine motor, vision/hearing, and personal/social/language	0–6 years	51	Sensitivity: 84.62% Specificity: 90.8% Validated against DDST
Denver developmental screening test-II (DDST-II) or/Denver-II	Gross motor, language, fine motor-adaptive, and personal-social. Also a behavior rating scale	0–6 years	123	Sensitivity: 83% Specificity: 43%
Baroda development screening test (BDST)	Motor and mental	0–30 months	54	Sensitivity and specificity: 65–95%
Bayley infant neurological screener (BINS)	Neurological intactness, receptive functions, expressive functions, and cognitive processes	3–24 months	72	Sensitivity: 65–75% Specificity: 60–80%

The formal developmental assessment tool presently available for use in India and considered to be the gold standard is Development Assessment Scale for Indian Infants (DASII). It is Indian adaptation of Bayley II, and has been standardized on Indian children. It assesses the motor and mental development of children between 0 months and 30 months of age. There are 67 items for assessment of motor development (includes gross and fine motor activities) and 163 items for assessment of mental development (includes cognitive, personal social and language skills). The developmental age of the index child is expressed at 3rd, 50th and 97th percentiles with reference to the study population. Developmental quotients (motor, mental and composite) are calculated using developmental and CA of the index child.

### Duration of Follow-up

Ideally, the follow-up of high-risk infants should be continued till adulthood, but in view of the feasibility in the clinical context, the same should continue at least till 8 years of age. Advice with regard to any increased risk for chronic diseases and maintaining healthy lifestyle with periodic screening should be provided prior to discharge from the high-risk follow-up.

### IN A NUTSHELL

1. It is imperative that a follow-up program for the high-risk infants be an integral part of the neonatal services.
2. The follow-up team is multidisciplinary comprising pediatrician, clinical psychologist, physiotherapist, occupational therapist, special educator, medical social workers and specialist from eye, ENT and genetics /neurology.
3. High-risk infants, especially preterms less than 32 weeks must have a screening CUS, ROP and hearing screening before discharge from the hospital.
4. Critical time periods for assessment of high-risk infants during follow-up are at ages 9–12 months, 15–18 months, 24–30 months and at 5–6 years.
5. For preterm infants, use corrected age when assessing for growth and development up to 2 years of age.
6. For assessing growth of preterm infants, use Fenton's charts till 40 weeks postconception age and the WHO-MGRS thereafter.
7. At each follow-up visit, assess for nutrition, growth, development and any medical problems.

# Section 15 NEONATAL INFECTIONS

**Section Editor** Siddarth Ramji

## Chapter 15.1

### Neonatal Sepsis

*Suman Chaurasia, Ramesh Agarwal*

Neonatal sepsis (NNS) contributes to substantial morbidity and mortality in newborn infants. Approximately, 20% of all neonates suffer from sepsis and about 1% succumb to it. Currently, sepsis accounts for nearly 28% of annual global deaths in the newborn period. Among the survivors, it is responsible for considerable neurodevelopmental sequelae, particularly in preterm infants (cerebral palsy in 10%), and is a cause of significant economic burden to the families, society and the nation at large. In resource poor settings, the costs of hospital-acquired infections divert precious resources that could be utilized for improving the access and quality of healthcare services. Additionally, after the initial admission, re-hospitalizations, long-term chronic illnesses and disabilities further inflate the expenses, often having a lifelong bearing upon the society.

#### DEFINITIONS

Neonatal sepsis refers to systemic infections affecting infants within 28 days of life and is usually of bacterial origin. It basically implies invasion of bloodstream by pathogens and may involve multiple organ systems. In common usage, the term covers bloodstream infections (BSIs) or septicemia, pneumonia, meningitis, urinary tract and bone/joint infections but does not include superficial infections.

**Neonatal sepsis (NNS) is classified in two different ways:**

*Based on culture positivity:*

1. Confirmed or culture positive sepsis—when sepsis is attributed to the pathogen isolated from clinical samples in the laboratory.
2. Clinical or culture negative sepsis—when sepsis is labeled based on clinical and/or other laboratory parameters in case the pathogen was not isolated.

*Based on age at onset:*

1. Early onset sepsis (EOS)—occurrence of sepsis before 72 hours of age.
2. Late onset sepsis (LOS)—occurrence of sepsis at or beyond 72 hours of age.

Healthcare-associated infection (HAI) is another term recently used in the context of NNS. The Centers for Disease Control (CDC) 2013 criteria defines it as any infection within health facility first suspected on or after the 3rd calendar (NOT hospital) day of admission to the facility (the day of hospital admission being calendar day 1). Note that all infections in infants resulting from passage through the birth canal during a hospital delivery are also included in the definition. HAI is further classified into device associated HAI (DA-HAI), which in neonates comprises of central

line associated BSI (CLABSI), umbilical catheter associated BSI (UCBSI), ventilator associated pneumonia (VAP) and catheter associated urinary tract infection (CAUTI).

#### EPIDEMIOLOGY

Neonatal sepsis is a major public health problem globally having high incidence and mortality in developing countries. NNS rates ranged from 6.5–38 per 1,000 live hospital-born babies in developing countries. These figures are 3–20 times higher compared to those in developed countries (1–5 per 1,000 live-births). In the community, NNS ranged from 49 per 1,000 livebirths in rural Guatemala to as high as 170 per 1,000 livebirths as in rural India. National Neonatal Perinatal Database (NNPD; 2002–2003) network in India reported HAI of 4% (67% being EOS, meningitis: 0.3–3%) in intramural and up to 40% in extramural infants.

Neonatal sepsis is commoner in infants with lower birthweight and gestational age. It is ten times commoner in those born with weight less than 1,500 g compared to infants with birthweight greater than or equal to 1,500 g. In the very low birthweight (VLBW) infants in the developing countries septicemia rates alone ranges from 20 to 41%. The data in hospital-days or device-days expressed from developing countries are rare; incidence densities of CLABSI and VAP are reported as 12.2 and 9.0 per thousand respective device days.

Infections in neonates kill nearly 11% of children around the world before their fifth birthday with around 40% (0.3 million) of them occurring in India alone. Of every three newborn casualties due to infections globally, one occurs in India; and approximately 42% of these die within the first week of life. Forty percent of septic infants have long-term sequelae, the most common being cognitive/learning difficulties or developmental delay (74%), cerebral palsy (36%), visual impairment (32%) and hearing impairment (10%). The risk increases further with lower birthweight/gestation age (nearly two-folds in culture positive VLBW infants), and depends also on causative pathogens [nearly fivefold with Gram negative sepsis in extremely low birthweight (ELBW) infants]; however it remains similar for early onset sepsis (EOS) or late onset sepsis (LOS).

#### ETIOLOGY

Major pathogens detected in HAI in developing countries are *Klebsiella pneumoniae*, *Escherichia coli*, *Pseudomonas* spp, *Acinetobacter* spp and *Staphylococcus aureus* (Table 1). The pathogen profile for EOS and LOS is largely identical. These patterns are in sharp contrast to the developed countries where group B streptococci (in term EOS and *E. coli* (in preterm EOS) dominate.

Many of these pathogens harbor high degree of antimicrobial resistance (AMR). Common first line antibiotics (ampicillin and gentamicin) no longer cover over 70% of hospital isolates. The AMR against third generation cephalosporins has soared from nearly 50% to around 80% over a decade in the gram-negative pathogens. Similarly, methicillin resistance, which is linked with broad range

**Table 1** Profile of pathogens of neonatal sepsis

Developing countries	Developed countries
1. <i>Klebsiella pneumoniae</i>	1. Group B streptococci <sup>a</sup>
2. <i>Acinetobacter</i> spp	2. <i>Escherichia coli</i> <sup>a</sup>
3. <i>Escherichia coli</i>	3. Coagulase negative staphylococci <sup>b</sup>
4. <i>Pseudomonas</i> spp	4. <i>Staphylococcus aureus</i>
5. <i>Staphylococcus aureus</i>	5. <i>Enterococcus</i> spp.
	6. <i>Listeria monocytogenes</i>

<sup>a</sup>more common in early onset sepsis; <sup>b</sup>more common in late onset sepsis

of antibiotics resistance in gram-positive pathogens, continues to prevail in over half of hospital isolates. Even the community strains have exhibited remarkable degree of AMR.

High antibiotic usage due to unregulated sale in health and other sectors (agriculture, animal husbandry) are the important reasons for evolution of the AMR epidemic. In fact, antibiotics—the most common drug prescribed in the neonatal intensive care unit (NICU), results in sustained high antibiotic exposure on the microbes—a stress termed as *antibiotic selection pressure*. This pressure coupled with poor hospital infection control practices favor the multidrug resistant pathogens to thrive rampantly in the Indian sub-continent. Recent evidence corroborates resistance elements like mobile genes [e.g., CTX-M15 and New Delhi Metallo-beta-lactamase-1 (NDM-1)] originating in India has high potential to transmit across species and genuses, and spread rapidly throughout the globe. Thus, AMR is fast acquiring universal dimensions requiring concerted efforts at the global level.

## RISK FACTORS

### Early Onset Sepsis

Early onset sepsis (EOS) is believed to be of maternal origin and generally indicate fetal infection (vertical transmission). Three mechanisms have been postulated—organisms are picked up during the passage through the birth canal, microbes ascending from the maternal perineum via a leak in the amniotic membrane (chorioamnionitis), or rarely, transplacental passage. Chorioamnionitis manifests clinically as intrapartum maternal fever (>38°C; essential criterion) plus any two of the following additional risk factors: maternal tachycardia (>100 bpm), fetal tachycardia (>160 bpm), uterine tenderness, and foul smelling liquor. Other important risk factors for EOS are low birthweight or preterm, and prelabor rupture of membranes more than 18–24 hours. Other risk factors reported include prolonged duration of labor (sum of 1st and 2nd stage > 24 hours), single unclean or more than three clean intrapartum vaginal examinations, asphyxia, male gender and not receiving intrapartum antibiotics. There are some 'extreme' risk factors that warrant early treatment: very prolonged rupture of membrane (≥ 72 hours), foul smelling liquor and documented ongoing maternal septicemia.

### Late Onset Sepsis

Late onset sepsis (LOS) is considered to be of environmental origin, the pathogen being acquired through care giving practices in homes and hospitals (horizontal transmission). LOS in the community results from poor hygiene/cord care, bottle feeding and prelacteal feeds. In hospital settings, besides low birthweight (< 2,500 g) or preterm (< 37 weeks), risk factors of LOS include:

- Admission to NICU
- Overcrowding and increased work loads
- Administration of IV fluids including parenteral nutrition
- Mechanical ventilation

- Invasive procedures including presence of central lines
- Unnecessary investigations or medications.

## PATHOGENESIS

Sepsis is believed to be an unusual systemic response to an ordinary infection. The manifestation of sepsis results from a complex interaction among host, pathogen and the environment.

Once a pathogen makes access into the local tissue, pathogen associated molecular patterns (PAMPs) like lipopolysaccharide (LPS—in Gram-negatives), lipoteichoic acid (LTA—in Gram-positive) or other cell wall products are released. PAMPs bind to the immune cells via receptors known as pathogen recognition receptors (PRRs) such as Toll-like receptors. Simultaneously, as a result of local damage, the host tissue release molecules (like high mobility group box-1 [HMGB-1], free DNA/RNA) known as damage associated molecular patterns (DAMPs). These together with PAMPs stimulate the innate immune response, which is generic in nature and is made up of chiefly tissue macrophages and complement systems. The pro-inflammatory response marked by release of cytokines [interleukin-6 (IL-6), interleukin-1-β, tumor necrosis factor-α (TNF-α)] and chemokines (interleukin-8) sets in. These potent molecules not only initiate but also amplify the interaction between the pathogen and host's immune system.

When the pathogen (or its products) is not contained locally and disseminates through the bloodstream, it leads to a systemic reaction via the pro-inflammatory response (systemic inflammatory response syndrome; SIRS). The immune system goes overboard to kill the spread of infection and manifests as clinical signs and symptoms of sepsis. Interestingly, in this wave to neutralize the attack, the overdriven immune system—often producing *cytokine storm*, may harm its own tissues and organ system. Thus, the host institutes the compensatory stage of anti-inflammatory response (CARS) as a possible protective measure.

However, the ensuing balance of pro- and anti-inflammatory is complex and may be associated with multiple organ dysfunctions (MOD)/shock—identified clinically as severe sepsis. It is not fully clear why this switch to CARS occurs in some and not in others. However, pre-existing immune dysfunction has been well recognized as an important determinant of severe sepsis.

As such, the neonatal host is born with underlying immune defect.

- In the innate system, they have decreased capacity of producing IL-6 and TNF-α. Instead, they are highly inducible to produce interleukin-10, an anti-inflammatory cytokine which also provides negative feedback to pro-inflammatory cytokine synthesis. The neutrophils and dendritic cells are not only lesser in number, but also functionally impaired. There is decreased activation of natural killer cells. The complement levels are barely the half of adult levels even at term gestation, implying defective opsonization and impaired bacterial killing.
- In the adaptive immunity, they have blunted pro-inflammatory immune (Th1) responses—an extension of adaptation in the intrauterine life. This signifies decreased cytotoxic function and isotype switching of B-cells leading to reduced cell mediated immunity. Besides, inherent memory deficit from limited pathogen exposure since birth, worsens it. Altogether, these features increase the neonatal susceptibility to intracellular pathogens. Further, neonatal immunoglobulin (except IgG) stores are low even at term, and over 50% of transplacental transfer occur only after 28–32 weeks. The spleen remains immature to handle capsulated organisms till 2 years of age.

With these limitations, the neonatal immune response does not conform to the stereotypical response to microbial invasion and manifests with more nonspecific features clinically compared to older children and adults.

## CLINICAL FEATURES

Neonatal sepsis presents with nonspecific and subtle features, which often overlap with common noninfectious conditions. Therefore, high index of suspicion is crucial for early identification of NNS. In fact, any clinical deterioration, especially of a previously well infant, should be viewed with a strong possibility of sepsis, particularly when other diagnoses are uncertain.

Alteration in feeding pattern is one of the most common findings manifesting as lethargy/poor activity, refusal to suck or unresponsiveness in a neonate who fed well before. In contrast to older children or adults, neonates do not mount fever easily. However, hypothermia ( $< 36.5^{\circ}\text{C}$ ) is a common manifestation, especially in preterm infants. Other features of autonomic system disturbances include: tachycardia or bradycardia, poor perfusion or delayed capillary refill, hypotonia or absent neonatal reflexes, and apnea or gasping respiration. WHO Young Infant Study (YIS) provided useful clinical signs and symptoms for diagnosis (**Table 2**).

Though a systemic condition, NNS often manifests with cluster of findings signaling predominant involvement of one or more organ systems:

- **Central nervous system (CNS):** Irritability, excessive crying, high pitched cry, seizures, bulging fontanelle (however, neonatal meningitis is usually silent).
- **Respiratory:** Tachypnea, retractions, grunting, apnea, cyanosis or increased ventilatory requirements.
- **Gastrointestinal tract:** Feed intolerance, abdominal distension, paralytic ileus, necrotizing enterocolitis, vomiting, diarrhea, jaundice (excessive or mainly conjugated) and hepatomegaly.

Late features include shock, sclerema (hide-like skin), disseminated intravascular coagulation (DIC) and pulmonary hemorrhage. Metabolic derangements may include hypo-/hyperglycemia, metabolic acidosis and hypocalcemia.

Early onset sepsis manifests commonly with respiratory symptoms, often having a fulminant course and less frequently as septicemia or meningitis. LOS presents as generalized septicemia with rapidly downhill presentation or may be localized to one organ system such as bone/joint infections with smoldering course. Evidence does not suggest a difference in the presentations of term versus preterm infants.

## DIFFERENTIAL DIAGNOSIS

Early presentation in sepsis can be confusing. One of the important differential diagnoses for EOS is perinatal asphyxia (findings in favor: difficult labor/birth; need for resuscitation; symptomatic soon after birth). Other common sepsis mimickers are hypoglycemia, temperature instability, respiratory distress syndrome and meconium aspiration syndrome.

## DIAGNOSIS

### Blood Culture

Isolation of pathogens remains the gold standard. It helps in tailoring the treatment based on the antibiogram. A properly

performed blood culture prior to start of antibiotics is a crucial step in the management. However, conventional culture methods (manual) have a long turn-around time and come positive in less than a third of suspected infants. The modern automated systems as BacT/Alert (biomerieux, USA), BACTEC [Beckton Dickinson (BD), USA] and LightCycler SeptiFast (Roche, Germany) have improved the initial reporting time as they detect the growth during initial incubation itself; but, being expensive, these are still unaffordable in most settings. Following important points concerning the blood culture need to be kept in mind:

- **Blood volume:** Nearly two-thirds of infants (0–2 months) with NNS have a colony count of less than 10 CFU/mL. Current evidence suggests optimum volume of blood to be inoculated at least 1 mL. Culture sample obtained from indwelling catheter is not advisable; though, sample drawn during fresh cannulation may be acceptable. Documenting negative bacteremia in a previously culture positive episode is unnecessary.
- **Choice of skin disinfectant:** Povidone-iodine (Betadine; desired concentration: 10%) and chlorhexidine (desired concentration: 2%) offer similar benefit. However, superior results can be expected if either agent is combined with alcohol (Isopropyl alcohol 70%). More importantly, the method of applying the solutions should be adhered strictly. Apply each solution in concentric circles with friction, and allow them to air dry between applications.

## Sepsis Screen

Sepsis screen is the most common test of sepsis work-up as it can be performed at the bedside. It is considered positive when any two or more of the following parameters exceed their cutoffs:

- **Total leukocyte counts (TLC)** less than 5,000/cmm.
- **Absolute neutrophilic count (ANC):** Its cut off is gestational age-specific and should be based on Manroe's and Mouzinho's charts in term and preterm infants, respectively; roughly less than 1,800/cmm in term babies.
- **Immature to total neutrophil ratio (I:T ratio):** 0.2 or more.
- **Micro-ESR ( $\mu\text{ESR}$ ):** Measured as fall in mm in first hour; 3+ age in days in the first week of life or more than 15 mm if older.
- **C-reactive protein (CRP):** It is the most popular and widely studied biomarker of sepsis. A cutoff of more than 10 mg/L or 1 mg/dL is widely accepted. However, commonly used latex agglutination qualitative test kits have a lower cutoff of 6 to 8 mg/L. A positive CRP test with these kits should be repeated using one part of the CRP reagent with two parts of serum that would effectively give a cutoff of more than 12 or 16 mg/L. A quantitative CRP has a higher cost but provides actual values and therefore is more meaningful.

Out of the indices in the sepsis screen, the most sensitive index is I:T ratio and most specific the CRP, but as a panel, none of them have good positive predictive value (PPV; 7–77%); though the negative predictive value (NPV) approaches nearly 100%. Therefore, sepsis screen should be viewed as a panel to *Rule Out* suspicion (rather than Rule In). A repeat sepsis screen 12–24 hours later, especially if the first screen was negative, would clinch the

**Table 2** Clinical features of neonatal sepsis (Young Infant Study)

Symptoms	Signs	
Difficulty in feeding	Temperature ( $> 37.5^{\circ}\text{C}$ or $< 36.5^{\circ}\text{C}$ )	Capillary refill time (CRT) $> 3$ sec
Convulsions	Heart rate ( $> 180/\text{min}$ or $< 100/\text{min}$ )	Lethargy/drowsiness
Movement only when stimulated	Respiratory rate ( $> 60/\text{min}$ )	Cyanosis
Diarrhea (watery stools)	Severe chest in-drawing	Bulging fontanelle
Pus from umbilical stump	Grunting	Abdominal distension
	Apnea	Multiple ( $> 10$ ) skin pustules

decision to start empirical antibiotics: if both tests are negative, sepsis is highly unlikely; if the latter one is positive, it is advisable to treat. The second test is taken as decisive on the basis of kinetics of CRP. It begins to rise only after 6–8 hours of onset of infection and could come negative if tested earlier.

### Lumbar Puncture

Indications of lumbar puncture (LP) include:

- *In EOS: If the infant is symptomatic or if blood culture comes positive.*
- *In LOS: Perform LP in all cases along with sepsis work-up.*

Lumbar puncture may be postponed in critically ill infants until stabilization. The interpretation of cerebrospinal fluid (CSF) findings is different in the newborn period and varies also with gestational age (detailed in chapter 15.3).

### Other Investigations

Culture of other sterile body fluids like urine, peritoneal/pleural/synovial tap should be considered on individualized basis. Of note, maternal cultures including high vaginal swab and blood culture is highly desirable in EOS. Other popular biomarkers of interest have more favorable kinetics; they are procalcitonin and interleukin-6. Former rises within 2 hours and later within minutes (Fig. 1). However, currently, they are not routinely used due to various limitations including the cost. Notably, procalcitonin has been found to be promising in adults and children but convincing evidence in neonates is still lacking.

### Radiology

These include chest X-ray (for pneumonia), abdominal X-ray [(for neonatal necrotizing enterocolitis (NEC)] or cranial USG/CT (for meningitis).

## MANAGEMENT

### Supportive Therapy

The spectrum of presentation of neonatal sepsis ranges from mild subtle features to catastrophic presentation. Infants can present with varying level of sickness ranging from mild to grave sickness. Optimal supportive care of the baby is as crucial as timely administration of antibiotics. Therefore, early identification and management of emergency signs should take precedence at presentation. Following points (T\_ABCDEFG\_MN) require to be addressed comprehensively in management of sepsis:

- **Temperature:** The infant should be nursed in the thermo-neutral zone and special attention should be paid to preterm infants where hypothermia is common.

**Figure 1** Kinetics of various markers of the inflammatory host response after endotoxin challenge in human volunteers

Abbreviations: IL-6, interleukin-6; PCT, procalcitonin; CRP, C-reactive protein. Reproduced with permission: Reinhart K, Meisner M, Brunkhorst FM. Markers for sepsis diagnosis: what is useful? Crit Care Clin. Jul;22(3):503-19, ix-x. 2006

- **Airway/Breathing:** Infant's airway should be aligned properly. Oxygen should be supplemented if required targeting normal saturation ranges (90–95%). Ventilatory support may be required in some infants.
- **Circulation:** Maintaining adequate tissue perfusion is important. Unexplained persistent tachycardia (at level higher than 20–30 bpm above baseline) is one of the earliest signs of shock. Initial fluid resuscitation comprises of one or two boluses of 10–20 mL/kg of normal saline over 20 minutes each. If shock persists, inotropic support is provided. Intake/output should be closely monitored.
- **Electrolytes and Fluids:** Maintenance fluid requirements should be carefully adjusted in view of total intake/output avoiding any fluid overload or dehydration. Serum electrolytes should be monitored in a sick infant.
- **Glucose and Metabolic monitoring:** Blood glucose level should be monitored. Metabolic acidosis should be borne in mind during resuscitation if response to inotropes is not up to the expectation. However, there is no role for bicarbonate therapy. Hypocalcemia should be actively looked for too.
- **Bleeding Diathesis:** It may be the underlying cause of shock or may manifest as full blown disseminated intravascular coagulopathy (DIC). While addressing with appropriate blood products including packed cells, platelet concentrates and fresh frozen plasma, vitamin K deficiency should be suspected if bleeding/DIC is not responding to adequate therapy.
- **Nutrition:** Nutritional support is vital. Breastfeeding/breast milk feeding should be permitted in a stable infant. Sick infants may require parenteral nutrition.

### Antimicrobial Therapy

Antibiotics are the cornerstone of management of neonatal sepsis. Typically, the management consists of two steps:

1. Empirical initiation providing a broad-spectrum antibiotics coverage, followed by
2. Subsequent review of therapy at 48–72 hours for one of the two purposes: de-escalating the therapy to narrower spectrum as per the culture report and stopping/continuation of same regimen if no pathogen is isolated (based on clinical scenario).

### Empirical Initiation

Timely administration of first dose of antibiotics is life saving for a septic infant. This implies that precautions should be taken to avoid any inadvertent delay in treatment of an infant due to transport/referral, initial clinical examination or investigations. Antibiotics often started provisionally, pending confirmation by definitive tests are known as empiric therapy. In principle, empiric regimen should provide broadest spectrum cover, essentially implying a combination of antibiotics covering both gram-positive and gram-negative pathogens. The actual choice of antibiotics should vary across the institutions depending on sensitivity profile of prevalent sepsis pathogens. Thus being unit-specific, a single empiric regimen cannot be universal. A simplified stepwise approach to decide on the choices of empiric antibiotics is outlined in **Box 1**.

### Subsequent Review

Because empiric therapy is a stop-gap arrangement, a review of the clinical scenario is warranted at 48–72 hours as two important events would have taken place in the meantime:

1. Report of culture(s) would have been available at bedside. Ascertaining the isolation of a non-contaminant is difficult but vital to management and should be based on review with clinical or microbiology team.
2. More importantly, the clinician would have sufficiently observed the infant for the therapeutic response, having completed a detailed review of history and examination.

**BOX 1 A step-wise approach for framing empiric antibiotics therapy for a unit**

1. Collate frequency table of isolates and their antibiogram of last 6–12 months
2. *First line antibiotics*: Combination of common antibiotic that together cover 60–70% of common isolates
3. *Second line antibiotics*: Other antibiotic combination (besides first line) to cover 80–90% of isolates.

**Note:**

- The antibiotics regimen needs to be reviewed every 6–12 months
- Cephalosporins are generally avoided for empiric regimen since they are known to rapidly induce ESBL (extended spectrum beta-lactamases)/cephalosporinases and are associated with high predilection for fungal colonization
- Reserve drugs as colistin, meropenem, vancomycin or linezolid should not be used empirically.

If the response to antibiotics is satisfactory then antibiotics need to be continued for 5–7 days, if cultures are sterile, and for 10–14 days for a culture positive episode (**Table 3**). De-escalation of the antibiotic options to one with narrowest spectrum out of the antibiogram and as monotherapy is essential. If there was worsening of symptoms or status quo, one may consider starting the second/third line of drugs and duration of therapy suggested is at least 7 days from the day of improvement.

**Important Issues for Antibiotics Therapy**

- Continuation of empirical antibiotic therapy without subsequently reviewing it in light of culture report and clinical response plus the course of illness is not only irrational but also dangerous. Evidence suggests empiric regimen continued for more than 5 days increases the mortality or NEC/LOS risk.
- Choose a combination of antibiotics (based on sensitivity pattern) if pathogens like *Pseudomonas* spp, *S. aureus* or *Enterococcus faecalis* have been isolated. If the pathogen is not reported to be sensitive to any of the tested antibiotics, a combination of two antibiotics with intermediate resistance (in highest doses) should be used. Extended antibiotic susceptibility test with rescue/reserve antibiotics may also be obtained.
- Cephalosporins (except 4th generation) should not be used to treat *Enterobacter* and *Citrobacter* even if they are reported to be susceptible because they produce inducible, chromosomally encoded cephalosporinases.
- In case the infant did not show the expected improvement even after instituting susceptible antibiotic options, antibiotic may be resistant in vivo. In such cases, reserve drugs' antibiotic susceptibility test (AST) should be requested. However, this should only be labeled resistant

after excluding all other known factors that can lead to nonresponse.

- In case infant did improve as expected on empiric antibiotics, but AST report shows resistance, one should suspect in vitro resistance, which should be discussed with microbiology team.
- To treat meningitis, antibiotics with reliable blood brain barrier penetration should be prescribed in highest doses with the goal to rapidly sterilize the CSF. For example, ciprofloxacin lacks good CNS barrier clearance; while vancomycin can reach CSF in adequate concentrations when meninges are inflamed but its doses should be increased as soon as concomitant meningitis is confirmed.
- In cases where culture is negative and laboratory evidence is unsupportive, empiric therapy should never be continued beyond 48–72 hours. However, it may be appropriate to give 7 days therapy for a critically ill infant at presentation where alternative causes do not explain the illness.
- Review the need for continuing antibiotics and adequacy of doses on daily rounds.

**Treatment of Asymptomatic Infants (Flow chart 1)**

Neonates exposed to perinatal risk factors (as described above) are predisposed to EOS. Thus, despite being asymptomatic, these infants require special attention. Empiric antibiotics should be started if the infant is exposed to clear cut chorioamnionitis. For other risk factors, a differential approach is required:

- *Infant of 37 weeks or more*: If adequate monitoring is possible (e.g., adequate nurse: patient ratio), *only close observation for 48 hours* would suffice to decide for discharge. If close monitoring is not possible, perform sepsis screen. If screen is positive, take blood culture. The infant is treated with antibiotics if both the screen and culture are positive; otherwise, wait and watch for 48 hours and discharge if they remained well.
- *Infant of less than 37 weeks*: Perform sepsis screen. If positive, draw blood culture and start empiric therapy. Use blood culture report to review decision of how long to *continue* antibiotics. But, if the sepsis screen is negative, wait for blood culture positivity report even for *initiating* treatment. If blood culture is negative, antibiotics may be deferred altogether.

**Adjunctive Therapy**

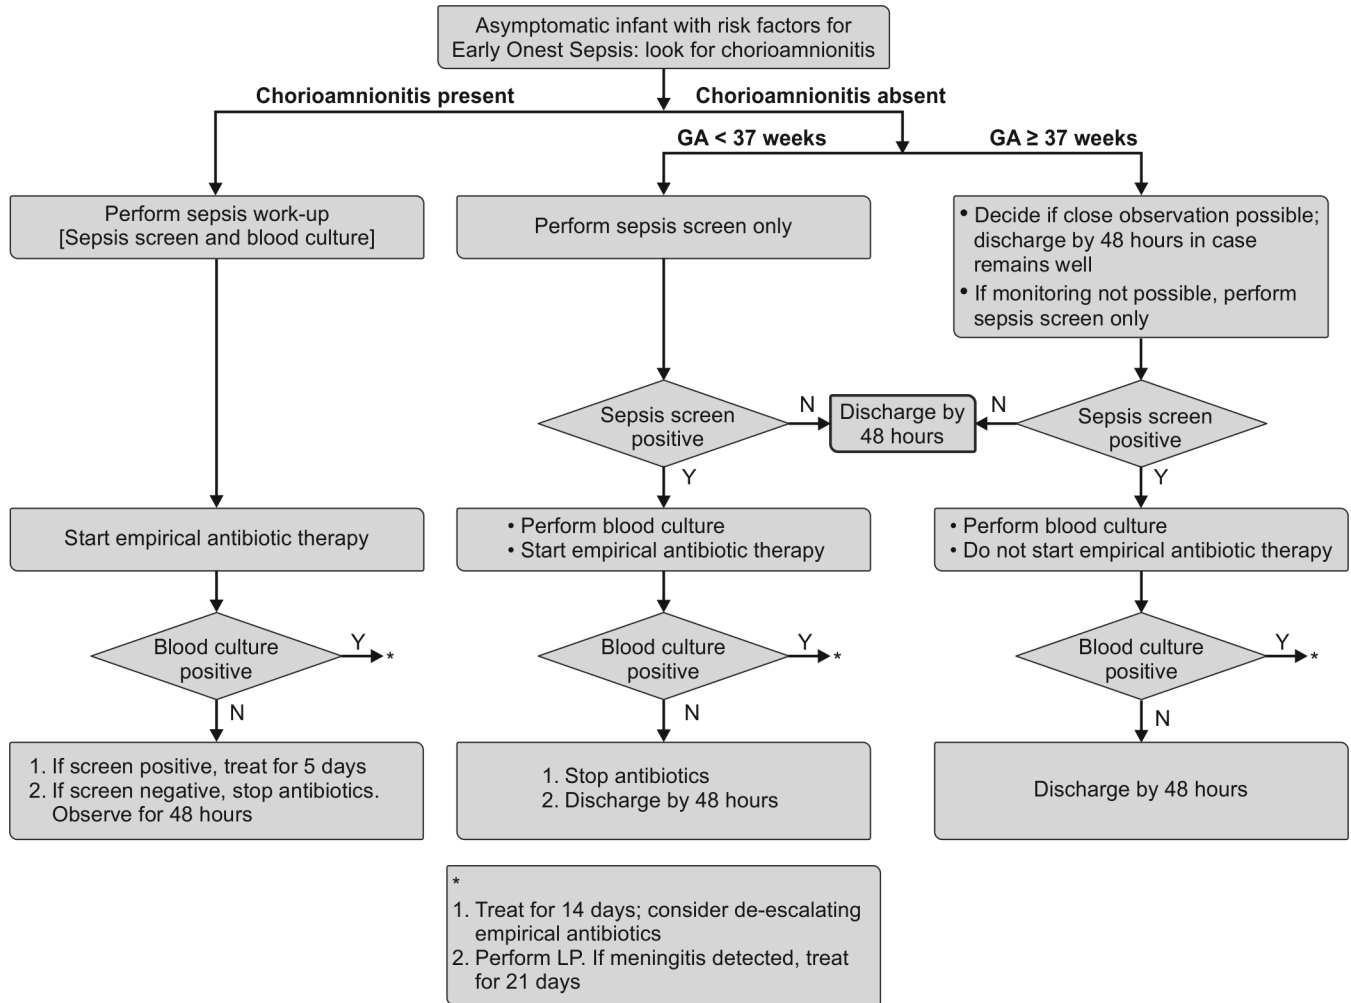

A variety of adjunctive therapies have been tried but none of them have worked well as of today. Therefore, for practical purposes, they have no role.

- *Intravenous immunoglobulins (IVIg)*: Current evidence does not favor the use of polyclonal or IgM-enriched IVIg.
- *Cytokine (Granulocyte colony stimulating factor (G-CSF)/Granulocyte-monocyte (GM-CSF)) infusion*: Similarly, either of these does not impart conclusive benefit in prophylaxis or treatment of sepsis and/or associated neutropenia.

**Table 3** Duration of antibiotic therapy

Condition	Duration	Remarks
Culture negative sepsis	5–7 days	
Culture positive sepsis	14 days	For coagulase negative Staph: when vancomycin therapy is started, duration of 7 days for septicemia and 14 days for meningitis is enough.
Meningitis (culture positive or negative)	21 days	See Chapter 15.3
Urinary tract infection	7–14 days	Once treatment is completed, start the infant on antibiotic prophylaxis (amoxicillin- 10 mg/kg/day or cephalixin 10 mg/kg/day OD) until vesicoureteric reflux is ruled out.

**Flow chart 1** Management of asymptomatic neonates born with risk factors of sepsis

- *Double volume exchange transfusion (DVET)*: Despite evidence of benefit in low quality study, robust evidence is still lacking for its efficacy.
- *Probiotics/prebiotics zinc*: Despite numerous recent studies, robust evidence to support definite benefit is still awaited.
- *Lactoferrin*: Prophylactic oral lactoferrin has been reported to reduce LOS (bacterial and fungal) in VLBW infants and more effective in ELBW infants; however, at present, generated evidence is insufficient to recommend the type, dosage, etc., precluding routine use.

## PREVENTION

Neonatal sepsis is preventable to a great extent by simple common sense approach. Primary prevention measures reduce the incidence of infections by controlling the risk factors (**Table 4**). Hand hygiene is the single most important preventive measure. Hand washing with soap and water is mandatory when visibly dirty or soiled with blood/body fluids. Otherwise, liberal hand rub (preferably alcohol-based) use in between patient contacts or whenever patient surroundings are handled should be adhered to.

**Table 4** Preventive measures

In the postnatal ward	In the nursery
Hand washing before contact by all caregivers	Strict hand hygiene policy
Keep cord dry	Aseptic work culture, no sharing of baby injectables/belonging
Promotion of exclusive breastfeeding	Thorough attention to general hygiene
Educating parents/guardians before discharge	Early enteral feeding
	Minimizing IV fluids or injections, catheters
	Abolishing unnecessary interventions (e.g., stomach wash, routine check for residual before feeding, unnecessary investigations) and promoting useful ones (e.g., Kangaroo mother care)
	IV and central line care ( <a href="http://www.cdc.gov/HAI/pdfs/bsi/checklist-for-CLABSI.pdf">http://www.cdc.gov/HAI/pdfs/bsi/checklist-for-CLABSI.pdf</a> )
	Quality improvement (QI) programs

### IN A NUTSHELL

1. Sepsis is an unusual systemic response to infection and contributes to about 28% of neonatal deaths.
2. Major pathogens causing hospital acquired infections in neonates in developing countries are *Klebsiella pneumoniae*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Acinetobacter baumannii*, and *Staphylococcus aureus* with a high rate of antibiotic resistance.
3. NNS presents with nonspecific and subtle features, which often overlap with common noninfectious conditions. Therefore, high index of suspicion is crucial for early identification of NNS.
4. Blood cultures should be taken in every suspected case of neonatal sepsis prior to start of antibiotics.
5. Sepsis screen panel has a low positive predictive value; prefer using a quantitative CRP for the panel rather than qualitative.
6. Even though antibiotics are started empirically, subsequent review after 48–72 hours is a must to de-escalate to narrow range antibiotic or even stop if baby is well and no pathogen is isolated. This will contribute to minimizing spread of antimicrobial resistance.
7. Hand hygiene is the single most important preventive measure for sepsis.

## Chapter 15.2

# Superficial Infections

Sriparna Basu, Ashok Kumar

Though apparently not life-threatening, superficial infections are a cause of concern for the parents and physicians. If neglected, local infections may spread and lead to systemic infection.

### SKIN INFECTIONS

Newborn's skin begins to colonize by microorganisms at birth. The organisms are almost similar to those found on adult skin. In the normal flora, *Staphylococcus epidermidis*, diphtheroids, streptococci, and coliform bacteria predominate. In preterm and hospitalized neonates, *Staphylococcus aureus* and *Candida albicans* are major organisms to get colonized and produce localized and disseminated diseases.

### Vesiculobullous or Pustular Lesions

Bacterial, viral and fungal infections in neonates may present with vesiculobullous or pustular lesions. The most important bacterial cause of superficial skin infections is *Staphylococcus aureus*. Other etiologic agents include streptococci, *Pseudomonas aeruginosa*, *Haemophilus influenzae* type b and *Listeria monocytogenes*.

### Staphylococcal Pyoderma

Staphylococcal infection leads to the formation of small vesicles, erythematous papules, pustules and large, fragile bullae filled with clear, turbid, or purulent fluid. The lesions develop after a few days of birth. The bullae get ruptured easily with formation of red, weeping, denuded areas with formation of crusts later on. Lesions may develop anywhere but are usually localized in the groin, axillae, periumbilical skin and back. The diagnosis is confirmed by Gram staining of the vesicular fluid showing Gram-positive cocci in clusters along with neutrophils and isolation of *S. aureus* on culture. If lesions are extensive or the infant appears ill, sepsis screen and a blood culture should be obtained prior to starting treatment. Methicillin-resistant *S. aureus* (MRSA) should be ruled out in hospitalized neonates.

**Treatment** If the lesion are small in size and few in number and the infant looks well, aseptic rupture of the pustule with sterile needle and cleaning with povidone-iodine should be done in hospital. Mothers can be instructed for application of topical antibacterial cream such as mupirocin. Maintenance of hygiene, such as daily infant bath or sponging, washing and sun-drying of clothes and bed sheets and hand washing should be emphasized. Application of oil should be avoided till the lesions heal. In multiple and/or large lesions oral antibiotic such as oral amoxicillin or cefadroxil for 7 days can be advised along with topical antibiotics and hygienic measures. Preventive measures are very important in sick hospitalized neonates to prevent disseminated infection and spread of the infection to others.

### Staphylococcal Scalded Skin Syndrome

The staphylococcal scalded skin syndrome (SSSS) is a severe bullous eruption, caused commonly by *S. aureus* (phage type group 2). The organism produces an exotoxin (exfoliatin) which has proteolytic activity on desmoglein-1 (a molecule found in the desmosomes of keratinocytes) which is responsible for the skin changes. SSSS is rarely seen at birth. Most neonates present between days 3 and 7 of life. Clinically, SSSS starts with a bright

erythema resembling a scald. The erythema usually begins on the face and gradually spreads downward with formation of blisters and bullae to involve the whole body, with accentuation in the flexural areas. The bullae are flaccid and rupture easily, progress rapidly into large areas of denudation. In extreme cases, the entire upper epidermis may be shed.

The level of cleavage is superficial. Histologic examination of the skin shows separation at the level of the granular layer with cell death and acantholysis without any inflammatory infiltrate. Crusting may be seen around the mouth and eyes. Conjunctivitis and hyperemia of the mucous membranes are common, but oral ulcerations are rarely seen. The lesions are painful and the infants are febrile and irritable. Gentle pressure applied to the skin leads to separation of the upper epidermis and skin wrinkling (positive Nikolsky's sign). In milder form of the disease, a scarlatiniform eruption is seen with perioral and flexural desquamation but without bullae formation or denudation.

Diagnosis is essentially clinical. Skin biopsy can differentiate SSSS from toxic epidermal necrolysis, where a subepidermal cleavage plane and epidermal necrosis are found. Cultures should be obtained from the nasopharynx, conjunctiva, umbilicus, denuded skin, blood, urine, and any other suspected foci of infection. Intact bullae are sterile.

**Treatment** Infants should be nursed in isolated rooms and all the precautions should be considered to prevent spread of the infection to other neonates. Treatment consists of prompt systemic administration of penicillinase-resistant penicillin, such as cloxacillin, nafcillin or oxacillin for 10–14 days along with strict fluid and electrolyte monitoring and replacement. Maintenance of nutrition by parenteral nutrition or nasogastric/orogastric feeding is vital. Vancomycin should be considered in patients who fail to respond to initial therapy or MRSA is suspected. Supportive skin care should be provided, with the use of skin emollients, such as creams or ointments. Healing occurs by flaky desquamation without any scar formation.

### Streptococcal Skin Infections

Infection with group B streptococci rarely produces skin lesions, though vesicles, bullae, and erosions have been reported occasionally. The lesions may be present at birth or develop later. Group A streptococcal infection occurs primarily as omphalitis or rarely as isolated pustules. The affected neonates should be treated aggressively with parenteral antibiotics (ampicillin and gentamicin for 10 days) as complications, such as, sepsis, cellulitis, meningitis, and pneumonia may occur.

### Listeriosis

*Listeria monocytogenes* infection can present as early or late onset sepsis and meningitis in newborns. Early form often presents with multiple pustules on the skin and mucous membranes.

### Mucocutaneous Fungal Infections

(Also See Chapter 33.3)

Mucocutaneous fungal infections are common in neonatal intensive care units. Increased survival rates of very low birth weight infants in association with an increased number of invasive procedures, widespread use of broad-spectrum antibiotics and simultaneous bloodstream infections often lead to concomitant superficial infections. Most fungal infections are caused by *Candida* spp, though a small number may also be attributed to *Malassezia*, *Zygomycetes*, or *Aspergillus* spp. *Candida albicans* is the most common cause of human candida infections, other pathogenic spp include *C. glabrata*, *C. parapsilosis*, *C. tropicalis*, *C. krusei*, *C. lusitanae*, and *C. stellatoidea*. Neonatal candidiasis usually develops after the first week of life secondary to the colonization of skin and mucosal

surfaces and commonly affects moist, warm areas, such as groin, or buccal mucous membranes. Common presentations include oral thrush and diaper dermatitis. Cutaneous lesions occasionally may be found over skin folds such as neck and consist of erythematous papules and vesicopustules which get confluent, forming a moist, erosive, scaly dermatitis with formation of satellite pustules. Rarely, paronychia lesions can also occur.

### Oropharyngeal Candidiasis (Oral Thrush)

Oral thrush presents as creamy white plaques in the mouth and may affect the lips, tongue, gums, and palate. The plaques do not scrape off easily. Forceful scraping of the lesions reveals erythema and bleeding at the base. Sometimes in more severe cases, lesions extend to pharynx or esophagus. Infants with thrush may be asymptomatic or may present with refusal to feed. Nipple of the nursing mother should be examined for nipple candidiasis which is usually bilateral. Nipples appear bright red and inflamed. Oropharyngeal candidiasis in the infant can be treated with nystatin oral suspension for 10–14 days or until 48–72 hours after resolution of symptoms. For preterm infants, dose is 0.5 mL (50,000 U) to each side of mouth 6 hourly; for term infants, dose is 1 mL (100,000 U) to each side of the mouth 6 hourly. In presence of candidiasis of the nipple, an antifungal cream should be applied over the nipples after each feeding for 2 weeks. The infant must be treated simultaneously.

### Candida Diaper Dermatitis

Candida diaper dermatitis appears as an erythematous rash in the inguinal region. The rash appears as areas of confluent erythema with multiple tiny pustules or discrete erythematous papules and plaques with superficial scaling. Satellite lesions are typical. In most cases topical application of antifungal cream is adequate, as dissemination is rare.

### Congenital Cutaneous Candidiasis

Congenital cutaneous candidiasis is a rare disorder resulting from a *Candida* spp. infection acquired in utero or during delivery. The manifestations appear at birth or within a few days with formation of pustules, vesicles, skin abscesses, or an erythematous maculopapular rash involving scalp, face, chest, abdomen, perineal area, extremities, or back. These lesions may lead to desquamation. Treatment depends on the extent of involvement. Topical antifungal agents from the imidazole group are the most effective if disease is limited to the skin. Systemic administration of amphotericin B, 5-fluorocytosine, or an imidazole is needed in patients with evidence of disseminated disease. Fluconazole or itraconazole for disseminated candidiasis in the neonate with low birthweight can provide an alternative to systemic amphotericin B and 5-fluorocytosine.

### Subcutaneous Fat Necrosis and Sclerema Neonatorum

*Subcutaneous fat necrosis* appears 1–4 weeks after delivery as well-circumscribed small nodules or large plaques. The lesions are usually localized on the cheeks, buttocks, back, arms, and thighs. The affected area is firm and tense to feel, and the overlying skin is reddish or violaceous. Histologically, a granulomatous reaction in the fat is seen, with formation of spiky crystals and infiltration of foreign body giant cells, lymphocytes, histiocytes and fibroblasts. Common causes of fat necrosis include perinatal asphyxia, hypothermia, shock, trauma, and hypercalcemia. Calcium may be deposited in the lesion, leading to ulceration and sinus formation. Management is the treatment of underlying cause. The lesions usually resolve in several weeks or months without complications. In areas where calcium deposition is seen, careful drainage should be done to lessen subsequent scarring.

*Sclerema neonatorum* is seen in sick neonates and is commonly associated with sepsis, hypothermia and other metabolic abnormalities. It is manifested as diffuse hardening of the subcutaneous tissue, resulting in a tight, smooth skin bound to the underlying structures. The skin is cold and firm to feel. In extensive involvement, whole body becomes stiff, face looks mask-like and joints become immobile. It is associated with high mortality. In case the infant survives, the cutaneous changes resolve by 2 weeks. Treatment with appropriate antibiotics guided by blood culture is essential. In infants who are severely ill, exchange transfusion has been tried, but the efficacy is not proven.

A number of viruses and *Treponema pallidum* (congenital syphilis) can also cause vesiculopustular or bullous lesions in the newborn. Common viruses include herpes simplex virus and varicella-zoster virus, but cytomegalovirus and coxsackie viruses can also cause vesiculobullous lesions.

## OPHTHALMIA NEONATORUM

Ophthalmia neonatorum or neonatal conjunctivitis, is an acute, mucopurulent infection of eyes, occurring in the first 4 weeks of life. The incidence varies from 1.6% to 12% of all livebirths. Previously, ophthalmia neonatorum was an important cause of neonatal blindness, *Neisseria gonorrhoeae* being the most common organism responsible. Availability of improved treatment and introduction of ocular prophylaxis with silver nitrate at birth has resulted in a dramatic reduction in the incidence of ophthalmia neonatorum and improved its prognosis.

### Pathogenesis

Normal conjunctiva contains non-keratinizing, squamous epithelium and thin, highly vascularized substantia propria with lymphoid tissue, plasma cells, mast cells, and macrophages. It also contains accessory lacrimal glands and goblet cells. Neonatal conjunctiva is particularly vulnerable to infection because of their inherent poor immune status and lack of local lymphoid tissue at birth. The inflammation of the conjunctiva results in dilation of blood vessels, chemosis, and increased secretion.

### Etiology

Various bacterial and viral infections may cause ophthalmia neonatorum (**Box 1**). The most common infectious agent is *Chlamydia trachomatis*. Chemical conjunctivitis, seen secondary to silver nitrate prophylaxis, has become less common after the use of erythromycin ointment for prophylaxis.

#### BOX 1 Causes of ophthalmia neonatorum

##### Bacterial

- *Chlamydia trachomatis*
- *Neisseria gonorrhoeae*
- *Streptococcus pneumoniae*
- *Staphylococcus aureus*
- *Staphylococcus epidermidis*
- *Streptococcus viridans*
- *Escherichia coli*
- *Pseudomonas aeruginosa*
- *Haemophilus influenzae*
- *Serratia marcescens*
- *Proteus*
- *Enterobacter*
- Other bacterial infections causing neonatal sepsis

##### Viral

- Adenovirus
- Herpes simplex virus

##### Chemical

### *Chlamydia trachomatis*

*Chlamydia trachomatis* is an obligate intracellular parasite and is the most common cause of infectious conjunctivitis accounting for approximately 40% cases of ophthalmia neonatorum. An infant born vaginally to a mother with chlamydial cervicitis has a 30–50% chance of developing conjunctivitis. The incubation period varies from 5 days to 14 days (typically 1 week after delivery), or earlier if membranes ruptured prematurely. The clinical manifestations vary from mild conjunctival infection with scanty watery discharge to severe mucopurulent conjunctivitis with eyelid edema, chemosis, and pseudomembrane formation. The eyes are usually less inflamed than in gonococcal infection. Most cases of chlamydial infections resolve spontaneously without complications. In untreated cases, superficial corneal vascularization and conjunctival scarring can occur. Loss of vision is rare.

### *Neisseria gonorrhoeae*

*Neisseria gonorrhoeae* is a gram-negative diplococcus and is the most virulent infectious cause of ophthalmia neonatorum. Gonococci can penetrate intact epithelial cells and multiply rapidly. The infection is acquired from the vaginal secretions of the mother at the time of birth. Transmission rate is higher in mothers with concomitant chlamydial infection. Presently, the incidence of gonococcal conjunctivitis has decreased substantially to less than 1%. It develops within 1–5 days of birth, but presentation can be delayed up to 2–3 weeks after delivery. The disease typically presents acutely with copious purulent discharge, profound chemosis, and edema of the eyelids. Eye discharge may also be blood-tinged with superficial conjunctival hemorrhages. If left untreated, gonorrheal conjunctivitis can lead to keratitis, conjunctival and corneal scarring, pannus formation, ulceration, panophthalmitis, permanent visual impairment and perforation of the globe within 24 hours. Affected infants should also be evaluated for disseminated gonococcal infection causing arthritis, sepsis and meningitis.

### Bacterial Conjunctivitis

Other gram-positive and gram-negative organisms, responsible for neonatal sepsis, can also cause ophthalmia neonatorum. *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Streptococcus viridans*, and *Staphylococcus epidermidis* are responsible for 30–50% of cases. Gram-negative infections are more common in preterm very low birthweight neonates. Infants present with a subacute onset between 4 days to 28 days of life. Common presentations include conjunctival redness with lid edema and varying amount of purulent discharge. Infections may also be acquired postnatally. Ophthalmia neonatorum caused by *Pseudomonas* is rare but infants may present with eyelid edema, redness and purulent discharge which may be severe and progress to corneal perforation, endophthalmitis, blindness, and even death.

### Viral Conjunctivitis

Viral conjunctivitis is characterized by acute onset at 6–14 days after birth and is most commonly caused by adenovirus and herpes simplex virus. Infants with adenovirus conjunctivitis present with petechial or large subconjunctival hemorrhages. Lymphadenopathy is associated in approximately 50% of cases. Infants with herpetic conjunctivitis present with unilateral or bilateral serosanguinous discharge with or without vesicular skin lesions. Lesions on the borders of the eyelids are commonly seen. Other ocular features, such as keratitis, anterior uveitis, cataract, retinitis and rarely optic neuritis may also be present. Infants should be examined for features of systemic infection, such as jaundice, hepatosplenomegaly, pneumonia, meningoencephalitis and disseminated intravascular coagulation.

### Chemical Conjunctivitis

Chemical conjunctivitis presents as a mild, purulent conjunctivitis within the first 24 hours of birth. It is most commonly associated with intraocular silver nitrate prophylaxis. Rarely, it may be seen secondary to prophylaxis with other agents (erythromycin or tetracycline). Chemical conjunctivitis is a self-limiting condition and does not require any diagnostic tests or treatment. The inflammation almost always disappears by 24–48 hours. It is rarely seen in our country since we do not advocate routine antibacterial ocular prophylaxis at birth.

### Investigations

History of genital discharge, genital vesicles, sexually transmitted diseases (STDs) in the parents and results of cervical swabs and cultures from mother during pregnancy or after childbirth should be obtained. If not done earlier, in suspected cases of STD, cervical cultures from the mother should be sent. Other STDs including HIV, hepatitis B and syphilis should be ruled out. Laboratory investigations in neonates have been summarized in **Box 2**.

#### BOX 2 Laboratory investigations in ophthalmia neonatorum

- Conjunctival scraping for Gram, Giemsa, and Papanicolaou stains
- Culture on chocolate agar and/or Thayer-Martin for *N. gonorrhoeae*
- Culture on blood agar for other bacteria
- Culture of corneal epithelial cells for HSV, in cases of corneal involvement
- Conjunctival scraping for polymerase chain reaction assay (PCR) and transcription-mediated amplification (TMA) to detect the infective organism
- Direct fluorescent antibody (DFA) studies
- Sepsis screen and other sepsis work-up to rule out neonatal sepsis and other STDs.

### Treatment

Because of the rapid progression of gonococcal conjunctivitis, treatment should be started promptly in suspected cases without waiting for culture results. Treatment may be altered once laboratory results are available. Eye patching should be avoided. Individual treatment options are summarized in **Table 1**. It should be remembered that blockage of nasolacrimal ducts are common in neonates and may result in thick and copious sticky or crusty discharge. The eye is not red and the infant looks otherwise well. The discharge may be intermittent and responds well to simple cleansing and regular nasolacrimal duct massage.

### Prevention

Several countries advocate the use of preventive ocular prophylaxis within 24 hours after birth. Medications include erythromycin 0.5% ophthalmic ointment, silver nitrate 1.0% solution, tetracycline 1.0% ointment and povidone-iodine 2.5% solution. All are considered equally effective against gonococcal conjunctivitis. There is no effective agent to prevent the transmission of *C. trachomatis*. Universal acceptance of ocular prophylaxis is controversial. Studies have shown that in places where the prevalence of maternal infection is low, routine eye prophylaxis is probably not worthwhile due to the high failure rates of the prophylactic regime.

In India, routine ocular prophylaxis is not advocated. After birth, both eyes should be cleaned with two separate sterile cotton balls soaked with normal saline from medial to lateral direction.

### Prognosis

Ophthalmia neonatorum usually responds to appropriate treatment, and the prognosis generally is good. Timely use of appropriate antibiotics has altered the prognosis of gonococcal

**Table 1** Treatment of ophthalmia neonatorum

Organism	Treatment
<i>Chlamydia trachomatis</i>	<ul style="list-style-type: none"> <li>• Oral erythromycin 40 mg/kg/day QID for 14 days.</li> <li>• Topical treatment alone is not adequate, and is unnecessary when systemic therapy is given.</li> <li>• Erythromycin may have a failure rate of 10–20% and some neonates will require a second or sometimes a third course of erythromycin.</li> <li>• A short course of oral azithromycin (20 mg/kg once daily for 3 days) might be an effective alternative, though, further studies are warranted.</li> <li>• Parents should be treated for <i>Chlamydia</i> infection.</li> </ul>
<i>Neisseria gonorrhoeae</i>	<ul style="list-style-type: none"> <li>• Infants should be hospitalized.</li> <li>• Intravenous or intramuscular single dose administration of ceftriaxone (25–50 mg/kg, to a maximum dose of 125 mg).</li> <li>• Frequent irrigation of the conjunctiva with sterile normal saline is needed.</li> <li>• Parents should be treated for gonorrhea.</li> </ul>
Bacterial conjunctivitis	<ul style="list-style-type: none"> <li>• Systemic antibiotics as used to treat neonatal sepsis along with topical antibacterials (aminoglycosides, polymyxin B sulfate-trimethoprim solution, macrolides, or fluoroquinolones).</li> <li>• In endophthalmitis, subconjunctival injections are occasionally required to salvage the eyes.</li> </ul>
Herpetic conjunctivitis	<ul style="list-style-type: none"> <li>• Systemic acyclovir (60 mg/kg in divided doses 3 times a day) for 14–21 days, with topical antiviral ophthalmic solution (1% trifluridine, 0.1% iododeoxyuridine, or 3% vidarabine).</li> <li>• Topical antibiotics should also be used to prevent secondary bacterial infections.</li> </ul>

conjunctivitis. Morbidity and mortality associated with neonatal conjunctivitis is proportional to the systemic involvement of the infecting agent.

## UMBILICAL CORD INFECTIONS (OMPHALITIS)

Omphalitis is defined as erythema of the umbilical stump with or without induration of the periumbilical area and purulent discharge. The infection may progress to abdominal wall leading to cellulitis, necrotizing fasciitis, myonecrosis, peritonitis, umbilical arteritis or phlebitis, hepatic vein thrombosis, and hepatic abscess. Severe cases are associated with high morbidity and mortality.

Omphalitis is rare in developed countries, where an overall incidence rate of 0.2–0.7% is reported. It is commonly seen in developing countries with incidence rates ranging from 2–54 per 1,000 livebirths in hospitalized neonates. Community-based rates for omphalitis are even higher. One study from Nepal reported an incidence of 105 per 1,000 livebirths. The incidence of case fatality rates following omphalitis ranges from 0 to 15%. Mortality increases significantly after the development of necrotizing fasciitis or myonecrosis. Predisposing factors for high incidence of omphalitis in developing countries are summarized below:

### In Community

- Lack of skilled birth attendants
- Sub-optimal use of infection control practices during and after birth—hand washing, disinfection of delivery surface and instruments, sterile cord cutting and cord tie
- Cultural practices involving application of unsafe substances to the cord
- Delayed health-care seeking behavior.

### In Hospitals

- Very low birthweight and prematurity
- Presence of risk factors for sepsis—chorioamnionitis or maternal infection, premature and prolonged rupture of membranes, poor maintenance of asepsis during delivery
- Umbilical catheterization
- Underlying anatomic abnormality, such as, patent urachus, omphalomesenteric duct, or urachal cyst
- Neonatal alloimmune neutropenia or congenital neutropenia
- Leukocyte adhesion deficiency.

### Pathogenesis

Umbilical cord usually separates between 5 days to 15 days after birth. The freshly cut umbilical stump is rapidly colonized after birth as the macerated tissue provides a good culture medium supporting bacterial growth. The profile of organisms colonizing the cord stump, pathogenic versus nonpathogenic, varies according to the hygienic conditions at the time of birth and immediate postpartum period. Colonized bacteria have the potential to invade the umbilical stump and surrounding tissue, leading to omphalitis. Initial superficial cellulitis may spread to the abdominal wall and infect the fascial planes, muscles and blood vessels, causing necrotizing fasciitis, myonecrosis, thrombophlebitis and disseminated sepsis.

### Causative Organisms

Most of the cases of omphalitis are polymicrobial in origin. Aerobic bacteria are present in approximately 85%. Anaerobes are recovered from one to two-thirds of infants. Common organisms are listed below. Neonatal tetanus caused by *Clostridium tetani* may also be associated with omphalitis.

### Organisms Causing Omphalitis

**Aerobic bacteria** *Staphylococcus aureus*, Group A *Streptococcus*, *Escherichia coli*, *Klebsiella pneumoniae*, and *Proteus mirabilis*.

**Anerobic bacteria** *Bacteroides fragilis*, *Peptostreptococcus* spp., and *Clostridium perfringens*.

### Clinical Manifestations

In full-term infants, the mean age at onset is 5–9 days. In preterm infants, the mean age at onset is earlier, at 3–5 days. The signs and symptoms of omphalitis depend on the extent of infections.

### Localized Infection

It consists of purulent or malodorous discharge from the umbilical stump, periumbilical erythema, edema and local tenderness. Recently, three case definitions (algorithms) have been standardized to describe the severity of omphalitis based on the extent of periumbilical erythema and absence or presence of pus.

- Algorithm 1: Moderate or severe erythema\*.
- Algorithm 2: Moderate erythema\* with pus, or severe redness (without regard to pus).
- Algorithm 3: Severe erythema\* with pus.

\*For erythema or swelling, severity has been graded as “mild” (limited to the cord stump only), “moderate” (affecting abdominal skin at the base of the stump < 2 cm), or “severe” (erythema spreading outward > 2 cm).

### Extensive Local Disease, with Extension

Necrotizing fasciitis or myonecrosis, initially located in periumbilical location and gradually spreading along the abdominal wall to the flanks, back, and scrotum. Petechiae, ecchymoses,

violaceous discoloration, bullae formation and crepitus may develop in local area.

### Systemic Disease

Hypo/hyperthermia, tachycardia, hypotension or delayed capillary refill, respiratory distress, necrotizing enterocolitis, jaundice, petechiae, or cyanosis, irritability, lethargy, poor feeding, hypo/hypertonia.

### Investigations

Complete sepsis screen including complete blood count with differential, immature-to-total (IT) neutrophil ratio, C-reactive protein, micro-ESR, blood culture for aerobic and anaerobic organisms, and lumbar puncture should be done. Gram stain and culture for aerobic and anaerobic organisms from umbilical discharge need to be taken. In myonecrosis, specimen should be obtained from involved muscle. Investigations necessary for supportive management include blood glucose, electrolytes including calcium, arterial blood gas analysis, renal function tests, coagulation profile, etc. Ultrasonography may show fascial thickening and fluid accumulation between subcutaneous fat and muscle in cases with fascial involvement.

### Treatment

Parenteral antibiotics cover both gram-positive and gram-negative organisms. A combination of antistaphylococcal penicillin, such as cloxacillin (vancomycin in suspected methicillin-resistant organism) and an aminoglycoside antibiotic (gentamicin or amikacin) is recommended. Omphalitis complicated by necrotizing fasciitis or myonecrosis requires coverage of anaerobic organisms also. Surgical debridement of the affected tissue and muscle in necrotizing fasciitis and myonecrosis may be life saving. It also helps to eradicate infection. Metronidazole or clindamycin may be added to provide anaerobic coverage. Antibiotics may be modified once culture reports are available. Duration of antibiotics depends on the severity of the disease; a minimum duration of 7–10 days is advocated.

Patients should be monitored for progression of disease. In uncomplicated cases, erythema of the umbilical stump improves within 12–24 hours after the initiation of antimicrobial therapy. Failure to respond suggests progression of the disease, presence of an anatomic defect, or an immunodeficiency state. Long-term follow-up is indicated as infants developing portal vein thrombosis may develop portal hypertension later.

### Prevention

The delivery should be conducted by skilled birth attendants adhering to clean delivery practices—to follow 5 *cleans* during birth, clean surface, clean hands, clean blade, clean cord tie and clean cord (dry umbilical cord care). Hygienic practices are important during postpartum period including hand washing

with soap and water before touching the baby both in community setting and in hospital. Since 1998, World Health Organization has advocated the use of dry umbilical cord care, i.e., keeping the cord clean without application of anything and leaving it exposed to air.

Recently, large community-based randomized trials have shown that application of 4.0% chlorhexidine (CHX) to the umbilical cord after birth can substantially reduce cord infection and neonatal mortality. Cochrane review demonstrates a reduction in incidence of omphalitis ranging from 27–54% depending on the severity of infection. Cleansing of the umbilical cord with CHX is considered safe and no significant adverse events associated with topical applications have been reported. The most prominent protective effects of CHX are seen during the first week of life.

### IN A NUTSHELL

1. The most important cause of neonatal superficial skin infections is *Staphylococcus aureus*. Other common etiological agents include streptococcal spp, *Pseudomonas aeruginosa*, *Haemophilus influenzae* type b, *Listeria monocytogenes*, Herpes virus, *Treponema pallidum* and *Candida albicans*.
2. Neonatal mucocutaneous candidiasis is common in very low birthweight neonates, usually develops after the first week of life and commonly affects oral mucous membranes and the diaper area.
3. Ophthalmia neonatorum, an acute, mucopurulent infection of eyes, occurs in the first 4 weeks of life and is a potential cause of neonatal blindness. Common organisms responsible are *Chlamydia trachomatis* and *Neisseria gonorrhoeae*.
4. Omphalitis, characterized by erythema and/or induration of the periumbilical area with purulent discharge from the umbilical stump, occurs due to poor infection control measures during and after birth.
5. If omphalitis is not diagnosed and treated early, the infection can progress to widespread abdominal wall cellulitis, necrotizing fasciitis, myonecrosis, peritonitis, umbilical arteritis or phlebitis, hepatic vein thrombosis, and hepatic abscess resulting in high morbidity and mortality.

## Chapter 15.3

# Meningitis in the Newborn

Kumutha Jayaraman, Manigandan Chandrasekaran

Newborn infants are more susceptible to meningitis than any other age group due to their immature immune system, which is deficient in humoral and cellular immune responses (mainly phagocytic and complement functions). There is an increased risk of neurological morbidity during childhood in those who have had neonatal meningitis. It is therefore imperative that meningitis in the newborn is diagnosed and treated early to prevent the adverse outcome.

## EPIDEMIOLOGY

The incidence of neonatal bacterial meningitis varies between 0.22 and 2.66 per 1,000 livebirths globally. The estimated incidence in the developing world is 126,000 cases annually. The highest occurrence is recorded from countries in sub-Saharan Africa and South Asia. The lower incidence in developed countries is mainly due to the widespread use of intrapartum antibiotic prophylaxis to prevent Group B *Streptococcus* (GBS) infection and widely available good supportive care. There are very few population-based surveillance studies on neonatal meningitis in South Asia, especially from India. Meningitis occurs in around 25% of neonatal infants with bacteremia. There are several risk factors associated with the development of bacteremia (**Box 1**).

### BOX 1 Risk factors for neonatal meningitis

#### Maternal risk factors

- Maternal chorioamnionitis (foul smelling liquor, maternal pyrexia and raised inflammatory markers)
- Prolonged pre-labor rupture of fetal membranes (> 24h)
- Maternal colonization with Group B *Streptococcus* (GBS)
- Low socio-economic factors

#### Neonatal risk factors

- Low birthweight
- Preterm birth
- Male gender
- Congenital CNS defects such as open spina bifida
- Invasive procedures like central vascular access, ventilation and presence of a shunt
- Co-existing infections like HIV infection

## ETIOLOGY

The causative organisms for neonatal meningitis are not different from those that cause neonatal sepsis. The age at presentation of meningitis can provide a clue to the probable mode of acquisition and the causative organisms. Early onset meningitis presenting within the first week (especially first 3 days) is most likely due to transmission from mother (vertical transmission). Late onset meningitis, presentation after the first week of life, suggests hospital or community acquisition. In India, the etiological organisms for both early and late onset meningitis are similar. However, in developed countries the etiology is different for the two types of presentation.

*Klebsiella* spp, *Staphylococcus aureus*, and *Escherichia coli* are the predominant causal organisms reported in India. The less common causative agents are *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae*, *Streptococcus agalactiae* (GBS) and *Listeria monocytogenes*. In neonatal infants, who have prolonged duration of hospitalization and invasive treatment,

meningitis may be caused by resistant gram-negative organisms, *Staphylococcus* and fungi. Resistant strains of *Staphylococcus* such as methicillin-resistant *S. aureus* (MRSA) and *S. epidermidis* (CONS) are increasingly being reported at present.

Group B *Streptococcus*, also known as *Streptococcus agalactiae*, is the leading cause for early onset meningitis in western countries, closely followed by *E. coli*. In late onset meningitis, *S. aureus*, CONS and gram-negative bacilli are the predominant causes. The other less common pathogens include *Listeria monocytogenes*, *S. pneumoniae*, *Enterobacter* spp, *H. influenzae*, *Citrobacter* spp, *Pseudomonas* spp and *Serratia* spp.

This difference in etiology can be attributed to a number of factors. India, being a semitropical country, bacteria like *S. aureus* and gram-negative bacilli grow easily while, relatively fragile bacteria like *H. influenzae*, *N. meningitidis* and *S. agalactiae* do not grow that well.

## PATHOGENESIS

The pathogenesis of neonatal meningitis has been studied extensively in animal models, and from observational studies of human cases. Newborn infants have deficiencies in specific and nonspecific immunity. Specific humoral immune deficiencies include lack of mucosal IgA and IgG in preterm infants born before 32 weeks gestation. There is a weakened production of these antibodies because of the immaturity of the antibody producing B cells and plasma cells, and decreased T- helper cells. Deficiencies in nonspecific immunity include impaired leukocyte chemotaxis, phagocytosis and bactericidal activity. Also, they have lower fibronectin concentrations that contribute to diminished opsonization and phagocytosis. These deficiencies are more prominent in preterm infants.

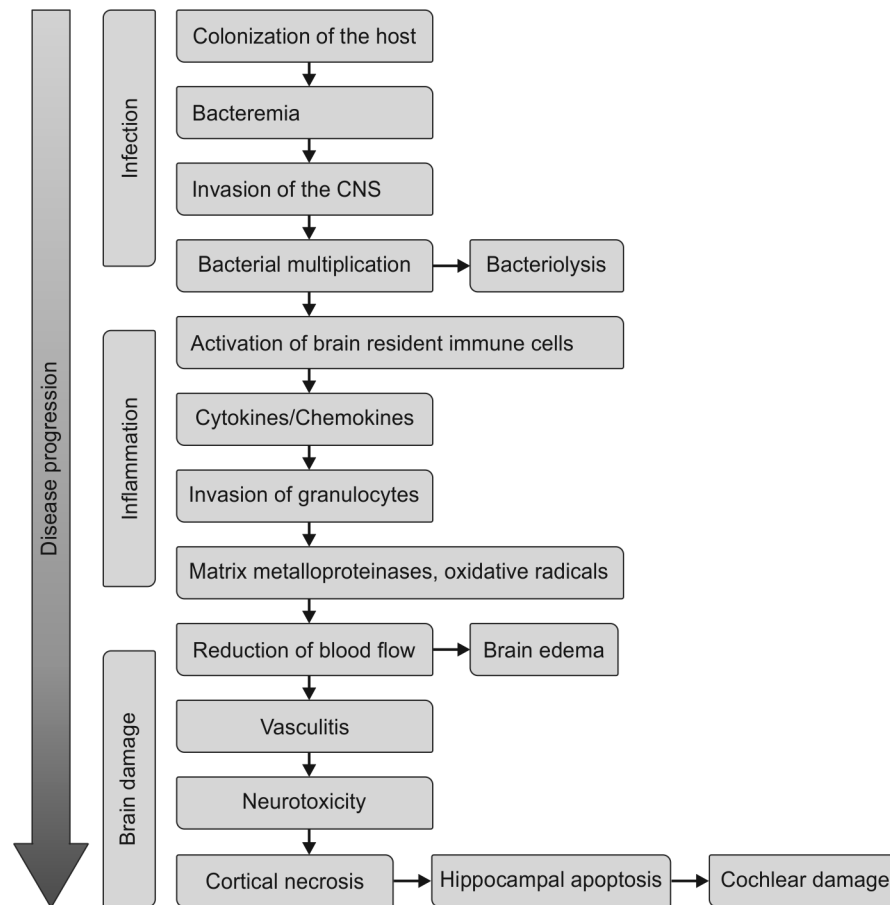

The pathophysiologic process starts with bacterial colonization and its invasion into central nervous system. This leads to multiplication of bacteria in ventricular and subarachnoid spaces, which in turn activates inflammatory cascade. This process, in combination with host factors, results in brain damage (**Fig. 1**).

The routes through which the meninges can be infected are hematogenous spread in generalized sepsis, focal infection with secondary bacteremia and direct inoculation from a congenital defect like open meningocele or dermal sinus. Some bacteria are associated with an increased predilection to cause neonatal meningitis because of their specific characteristics. Those that are closely linked to meningitis are the capsular polysaccharide of GBS type III, K1 antigen of *E. coli*, and *L. monocytogenes* type IVb.

The steps involved from colonization to CNS invasion of the bacteria are described in **Flow chart 1**. Bacterial adhesins are necessary for optimal adhesion of bacteria to the mucosal epithelium and specific endopeptidases (secreted by bacteria) inactivate secretory IgA antibodies. The bacteria enter the mucosal barrier through or between the epithelial cells. Once in the systemic circulation, the polysaccharide capsule of the pathogen aids in the survival in the blood by mediating resistance to complement-mediated lysis and phagocytosis by polymorphonuclear (PMN) leukocytes and macrophages. Finally, the pathogens cross the blood brain barrier transcellularly or paracellularly to reach the CNS.

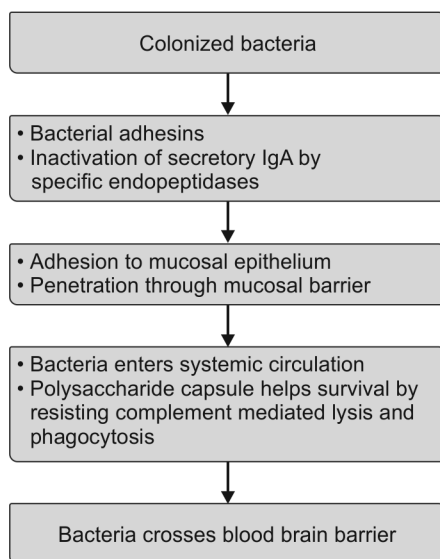

There is rapid multiplication of bacteria in the brain due to the impaired host defense mechanisms at the blood brain barrier. When bacterial growth reaches the stationary phase or when antibiotics start working, bacteriolysis occurs releasing various bacterial components including lipopolysaccharides and peptidoglycans which trigger the inflammatory reaction locally. Immune system in the CNS, including macrophages, dendritic cells and microglia cells, activate brain cells to produce inflammatory cytokines such as IL-1 $\beta$ , TNF- $\alpha$ , and IL-6. CSF pleocytosis also happens as a result of this immune recognition. This inflammatory reaction

**Figure 1** Progression of meningitis

**Flow chart 1** Invasion of CNS by the bacteria

and cellular activation result in release of several inflammatory mediators such as matrix-metalloproteinases and reactive oxygen species, both of which play a key role in the development of brain injury. The resultant pathophysiological events include microglial proliferation, cerebral vasospasm, thrombosis and release of excitatory amino acids and free radicals.

The pathological changes observed in infants with meningitis include cerebral edema, subdural effusion, ventriculitis, gliosis, infarction, cortical necrosis, multicystic encephalomalacia, hippocampal apoptosis and cochlear damage.

## CLINICAL FEATURES

Clinical presentation of neonatal meningitis is often subtle, nonspecific, atypical and not different from that of sepsis. The most commonly reported symptoms are fever, lethargy, poor feeding, irritability, seizures and respiratory distress. They can also present with hypothermia, apnea, pallor, respiratory failure and shock. Neurological symptoms and signs, which include stupor, seizures, bulging anterior fontanel, extensor posturing/opisthotonus (**Fig. 2**), nuchal rigidity (very rare) and focal cerebral signs, are less often observed but could be late signs of neonatal meningitis.

The clinical features may be affected by other factors such as gestational age, prior antibiotic treatment and postnatal age. There are no data available currently on timing of onset of these clinical features. Hence, the clinician should have a high index of suspicion of meningitis when evaluating a sick newborn infant.

## DIFFERENTIAL DIAGNOSIS

The clinical features for neonatal meningitis are nonspecific and a variety of other conditions share similar clinical presentation. The clinical picture in neonatal meningitis, in addition to sepsis, may also be due to other noninfectious conditions of the newborn infants. It is important to rule out cardiac and metabolic conditions

**Figure 2** Baby showing opisthotonus posturing

when an infant presents with respiratory distress, lethargy and poor feeding with or without shock. The neurological features of meningitis such as seizures and tone abnormalities could also be due to hypoxic ischemic encephalopathy, hemorrhage, stroke and cerebral edema. Hence, it is important to elicit careful history and perform complete clinical examination in all sick newborn infants.

## APPROACH TO DIAGNOSIS

The definite diagnosis of neonatal meningitis is often difficult as clinical signs are nonspecific and only 30–50% of cases of meningitis have positive blood culture. Lumbar puncture (LP) to examine the cerebrospinal fluid (CSF) is the only way to confirm the diagnosis of meningitis. A comprehensive evaluation of CSF includes gram-stained smear examination, bacterial culture, cell count with WBC differential examination, and quantification of glucose and total protein. Normal values for CSF indices (**Table 1**) are different from that of older children and adults.

Normal polymorphonuclear cells will be around 60% of WBC count in CSF. CSF glucose is usually 70–80% of plasma glucose with the minimum normal value of 50%. Hence, it is important to measure plasma glucose just before performing LP.

Positive CSF culture confirms the diagnosis, while raised WBC count with predominant polymorphonuclear leukocytes, raised protein and low glucose (hypoglycorrhachia) supports the diagnosis of meningitis. These CSF abnormalities are more marked in gram-negative meningitis than those cases caused by GBS or *Listeria monocytogenes*. Treatment is initiated if CSF WBC count is more than  $10/\text{mm}^3$  or glucose less than 25 mg/dL or protein more than 170 mg/dL in preterm infants, and CSF WBC count more than  $8/\text{mm}^3$  or glucose less than 20 mg/dL or protein more than 120 mg/dL in term infants. Clinical judgment will have to be used if results are inconclusive.

The indications for performing CSF examination in newborn infants remain debatable, particularly in infants with no neurological signs or those not severely ill. Many recommendations have suggested that CSF examination should be

done in any newborn infant with suspected sepsis along with blood culture, as around 25% of cases of sepsis were associated with meningitis. However, recent studies have questioned the need for CSF examination in all neonates with suspected sepsis, especially in well infants with risk factors for sepsis who are under 1 week of age. The incidence of meningitis in early onset sepsis is low and the yield from routine CSF analysis in the first week of newborn life is also low. CSF examination should be part of the septic work-up in late onset disease. The contraindications for performing CSF examination are not many; it should be avoided in hemodynamically unstable infants and in those with thrombocytopenia.

Timing of LP is crucial in the interpretation of CSF results. In the presence of meningitis, CSF culture and Gram stain could become negative if LP was performed after administering antibiotics. However, CSF pleocytosis and raised protein may persist for days even after commencing antibiotic course. Hence, it is important to perform LP before antibiotic administration whenever possible, to get correct results. Furthermore, once CSF is collected, it should be analyzed as soon as possible or within 30 min of collection. It has been shown that WBC count and glucose in CSF rapidly fall with time.

The need to repeat LP after 48 hours of antibiotics is controversial. However, many recommend it, as it may have therapeutic and prognostic implications. Delayed clearance of a microorganism, when associated with no or partial clinical improvement, could indicate antibiotic resistance or a complication of meningitis such as brain abscess. Repeat LP is not recommended for those who are making good clinical recovery and the causative organism is susceptible to the given antibiotic treatment. It is recommended for those who have persistent pyrexia and raised acute phase reactants, and clinical deterioration with new neurological findings.

At times, common complication of LP can be traumatic tap. Several calculations and formulae have been proposed and studied, but none of them have provided a consistent result towards diagnosing or excluding meningitis in pediatric population, especially in newborn infants. Hence, once the traumatic LP is obtained, it is important to continue the antibiotic treatment, and then await the culture results. If LP is needed in desperate situations such as strong clinical suspicion, presence of neurological signs and positive blood culture, the procedure can be repeated 24 hours after the traumatic tap.

## OTHER INVESTIGATIONS

Blood culture is usually positive, as neonatal meningitis is commonly associated with or secondary to sepsis. However, it has been shown that around 15% of cases of neonatal meningitis with positive CSF culture may have negative blood cultures.

Nucleic acid amplification tests such as polymerase chain reaction (PCR) assays have been assessed for detecting the presence of bacterial DNA in CSF from infants with bacterial meningitis. Studies suggest a high diagnostic value in detecting microorganisms such as *H. influenzae*, *S. pneumoniae* and *N. meningitidis*. However, data on detection of GBS and *L. monocytogenes* is limited. Before considering implementing this test as a routine part of investigation, more information is needed on the cost effectiveness, prognostic value and usefulness in India.

## Cranial Ultrasound

Ultrasound should be performed initially as a baseline study in cases of neonatal meningitis and should be followed up with repeat scan if any clinical deterioration occurs or rapid increase in head circumference is noted (**Figs 3 and 4**). Complications of meningitis such as ventriculitis, secondary hemorrhage, infarction, hydrocephalus pyocephalus and abscess can all be assessed through ultrasound.

**Table 1** Normal CSF indices for newborn infants (means, range)

Newborn infants	White blood cells ( $\text{mm}^3$ )	Protein (mg/dL)	Glucose (mg/dL)
Preterm	10 (0–30)	100 (50–300)	50 (24–63)
Term (less than 7 days old)	5 (0–20)	60 (30–250)	52 (34–119)
Term (more than 7 days old)	3 (0–10)	50 (20–80)	52 (34–119)

### Computed Tomography Scan

Computed tomography scan is valuable at all stages of neonatal bacterial meningitis. In the acute stage, CT scan may provide information regarding the degree of cerebral edema (small size of ventricles), the occurrence and site of block to CSF flow (dilated ventricles) (**Figs 5A and B**), major infarction (cerebral area of increased or decreased attenuation, depending on the hemorrhagic component to the infarction), the type of associated encephalopathy (e.g., periventricular hypo-attenuation secondary to periventricular leukomalacia), and the presence of abscess or subdural collection. In a study of 45 infants with neonatal gram-negative bacterial meningitis, CT findings were normal in only 30%, demonstrated hydrocephalus in 44%, changes consistent with ischemic lesions in 29%, abscess in 18%, and subdural effusion in 7%.

### Magnetic Resonance Imaging Scan

Magnetic resonance imaging scan is recommended for infants with focal neurological abnormalities, persistent infection or clinical deterioration. It is the imaging method of choice for identifying lesions such as ventriculitis, hydrocephalus, subdural empyema, brain abscess and thrombosis. In addition, diffusion-weighted

MRI shows ischemic lesions and brain edema more effectively and earlier than CT scan. Identifying these complications early will facilitate in early management and influencing the outcome positively.

### TREATMENT

Early diagnosis and prompt treatment is essential in the management of neonatal meningitis in order to prevent adverse outcome. Treatment is divided into three parts, supportive treatment, antibiotic treatment and adjunctive treatment.

### Supportive Treatment

The survival of a sick newborn with meningitis depends upon aggressive supportive care. Care should be taken to avoid hypo or hyperthermia and the infant should be nursed in a thermoneutral environment. Oxygen saturation should be kept in the normal range and assisted ventilation may be needed for respiratory support on some occasions. In cases of septic shock, adequate fluid resuscitation is important in the management for improved survival. Furthermore, inotropes may be required for maintaining normal blood pressure. Septic shock remains one of the risk factors

**Figure 3** USG cranium coronal section at the level of frontal lobe showing ventricular dilatation and turbid CSF, pyocephalus

**Figure 4** USG cranium coronal section at the level of parieto-occipital lobe showing ventricular dilatation and turbid CSF, pyocephalus

**Figures 5A and B** Axial CT with contrast showing ventricular dilatation with marginal contrast enhancement, ventriculitis

for poor outcome in cases of neonatal meningitis. Blood products like platelets and fresh frozen plasma may be needed to correct thrombocytopenia or coagulation abnormalities. The infant should be monitored for hypo or hyperglycemia regularly and need to be treated accordingly. Early recognition and prompt referral to the appropriate healthcare delivery system is vital.

## Antibiotic Treatment

This is the specific treatment for neonatal meningitis. Early use of appropriate antibiotics is vital for a good outcome. The antibiotic treatment should cover likely pathogens and have excellent CSF penetration. The decision on selecting the antibiotic depends on current local prevalence and antibiotic resistance profile of pathogens. The safe combination therapy for suspected meningitis would probably be ampicillin, gentamicin or amikacin and a third generation cephalosporin (such as cefotaxime). This combination is likely to cover the probable pathogens such as gram-negative bacilli, *Staphylococcus*, GBS and *L. monocytogenes*. However, it is best to have one's own unit-specific antibiotic policy based on the profile of locally prevalent pathogens and antibiotic sensitivity. If meningitis is likely to be hospital acquired, cloxacillin or vancomycin should be considered to cover *Staphylococcus* in addition to aminoglycoside and cefotaxime. It is probably prudent to use vancomycin in the combination for suspected hospital-acquired infections as they are usually caused by CONS and MRSA. In late onset meningitis, resistant gram-negative bacilli are common, so, a third generation cephalosporin along with an aminoglycoside would be a better combination to treat than others. Third generation cephalosporins are effective against major pathogens of neonates and it has been used worldwide for the same purpose. They have good CSF penetration. Cefotaxime is often preferred in neonatal infections than ceftriaxone as ceftriaxone can cause jaundice (and kernicterus) by having high affinity for albumin. The suggested empirical antibiotics are listed in **Table 2**. Empirical therapy should be upgraded to second line if clinical improvement fails to occur or new signs appear in 48 hours after starting first line treatment.

**Table 2** Empirical choice of antibiotics for treatment of neonatal meningitis

Clinical scenarios	Antibiotics
First line Early onset/community acquired	Ampicillin, gentamicin or amikacin, and cefotaxime
Second line Hospital acquired or resistant strains likely	Cloxacillin or vancomycin, and gentamicin or amikacin, and cefotaxime

The choice of antibiotics for definitive therapy, once the pathogen is known (positive CSF and/or blood culture), is usually straightforward. Suggested antibiotics for specific microorganisms are mentioned in **Table 3** and the doses in **Table 4**.

The duration of antibiotics in neonatal meningitis has been discussed widely in literature. Currently, there is little evidence to guide the exact duration of antibiotics for neonatal meningitis. However, it is largely recommended that antibiotics should be given for at least 3 weeks for all cases of neonatal meningitis. This duration should be considered as a minimum duration as in some cases, it might need to be extended further. It is important to monitor the following during treatment—head circumference measurement twice weekly, and daily neurological examination to detect any focal neurological deficits. Cranial ultrasound in the first week and at the end of antibiotic therapy should be performed to look for ventricular size, ventricular wall enhancement, midline shift and intraventricular debris. The use of intraventricular antibiotics has been evaluated in several studies. However, Cochrane review recommends avoiding intraventricular antibiotics as a part of treatment in neonatal meningitis.

## Antibiotic Resistance and Newer Antibiotics

Antibiotic resistance is a major problem worldwide with local variations. *Staphylococcus* and *Pneumococcus* resistance to antibiotics has been reported in both developing and developed countries. In India, increasing antibiotic resistance has been reported, particularly for gram-negative organisms to first line antibiotics. This could be ascribed to several factors such as indiscriminate use of antibiotics and lack of surveillance. Newer antibiotic like cefepime, a fourth generation cephalosporin, has greater stability against  $\beta$ -lactamases and better CSF penetration than ceftriaxone. Cefepime has broad-range of activity against most bacteria causing meningitis. Carbapenems such as meropenem and imipenem possess the widest range of activity against gram-positive and gram-negative bacteria. The safety and efficacy of meropenem is similar to that of third generation cephalosporins. Fluoroquinolones (gatifloxacin and moxifloxacin) have good CSF penetration and better in vitro sensitivity against gram-positive bacteria than many antibiotics. Tigecycline, a glycylglycyl antibiotic, is active against many gram-positive and gram-negative bacteria. Aztreonam (for gram-negative organisms) and linezolid (for gram-positive organisms) are emerging antibiotics that have shown promising results in the treatment of meningitis. These antibiotics should be used cautiously, and only in cases of meningitis caused by resistant microorganisms.

**Table 3** Specific antibiotics for bacterial meningitis based on causative microorganism

Microorganisms	Recommended antibiotics	Alternative antibiotics
Enterobacteriaceae ( <i>E. coli</i> and <i>Klebsiella pneumoniae</i> )	Cefotaxime and gentamicin/amikacin	Meropenem, aztreonam, ciprofloxacin
<i>Staphylococcus aureus</i> (methicillin sensitive)	Flucloxacillin	Vancomycin, meropenem
<i>Staphylococcus aureus</i> (methicillin resistant)	Vancomycin	Linezolid
<i>Staphylococcus epidermidis</i> (CONS)	Vancomycin	Meropenem
<i>Streptococcus agalactiae</i> (GBS)	Ampicillin or penicillin G and gentamicin	Cefotaxime, ceftriaxone, vancomycin
<i>Listeria monocytogenes</i>	Amoxicillin/Ampicillin or penicillin G and gentamicin	Trimethoprim-sulfamethoxazole
<i>Streptococcus pneumoniae</i>	Ampicillin or penicillin G	Cefotaxime, cefepime, meropenem
<i>Pseudomonas aeruginosa</i>	Ceftazidime or cefepime	Aztreonam, meropenem
<i>Acinetobacter baumannii</i>	Meropenem	Colistin, polymyxin B

**Table 4** Recommended doses of commonly used antibiotics in neonatal meningitis

Antibiotics	Preterm ( $< 7$ days of age) mg/kg/dose	Preterm ( $> 7$ days of age) mg/kg/dose	Term (0–7 days of age) mg/kg/dose	Term ( $> 7$ days of age) mg/kg/dose
Ampicillin	100 twice daily	100 thrice daily	100 thrice daily	100 four times daily
Amikacin	15 once daily	7.5 thrice daily	10 twice daily	10 thrice daily
Cefotaxime	50 four times daily	50 four times daily	50 four times daily	50 four times daily
Ceftazidime	50 twice daily	50 thrice daily	50 thrice daily	50 thrice daily
Ceftriaxone	50 once daily	50 once daily	50 once daily	75 once daily
Gentamicin	2.5 twice daily	2.5 thrice daily	2.5 twice daily	2.5 thrice daily
Cloxacillin	50 twice daily	50 thrice daily	50 thrice daily	50 four times daily
Penicillin G	1,00,000 U twice daily	1,00,000 U thrice daily	1,00,000 U thrice daily	1,00,000 U thrice daily
Meropenem	40 twice daily	40 thrice daily	40 twice daily	40 thrice daily
Vancomycin	15 twice daily	15 thrice daily	15 twice daily	15 thrice daily

## Adjunctive Treatment

### Steroids

The pathophysiology of brain injury in meningitis involves series of inflammatory reactions and correlates with severity of inflammation in CSF. The use of corticosteroids in meningitis has been studied extensively in animal models as well as in children and adults with meningitis. A recent systematic review, which included 44 studies, concluded that corticosteroids significantly reduced hearing loss and neurological outcome in developed countries, but did not reduce mortality. There are limited information available based on neonatal studies. One RCT from Jordan showed no benefit from the use of corticosteroids. However, a recent study from India, which included 80 newborn infants, showed significant reduction in mortality in the corticosteroid group. But, there are several limitations in the study including methodological issues. Hence, corticosteroids cannot be recommended for neonatal meningitis on the basis of current evidence.

### Glycerol

An osmotic diuretic, has been shown to increase plasma osmolality in children with meningitis, which in turn reduce cerebral edema. A recent study from South America showed that it was effective in preventing severe neurological sequelae in children with bacterial meningitis. However, a randomized clinical trial from Malawi on adults with meningitis showed that glycerol was harmful with increased mortality. Furthermore, there are no studies of its use in neonatal meningitis.

## OUTCOME

The mortality rate is high in neonatal meningitis, but it varies with the nature of the organism, the age of the infant and the quality of care provided. In developed countries, overall mortality rate in neonatal meningitis has fallen over recent decades from 50% in 1970s to less than 10% in recent years. However, in developing countries, mortality remains high in the range between 40–58%. The poor prognostic factors are listed in **Box 2**.

### BOX 2 Poor prognostic factors for mortality in neonatal meningitis

- Male sex
- Prematurity
- Low birthweight
- Meningitis due to gram-negative organism
- Delay in diagnosis and initiation of antibiotic treatment.

The incidence of neurological sequel ranges from 40–55% as reported from various studies in India, while around 20–30% in developed countries. The spectrum of neurological sequel in India is similar to that of developed countries. The adverse outcome following bacterial meningitis is mentioned in **Box 3**. There are several risk factors that can predict later adverse neurological outcome. These factors include young age at presentation, low birthweight, need for inotropes to maintain blood pressure, focal neurological deficits, seizures lasting for several days, under nutrition, delay in starting treatment, abnormal cranial ultrasound findings (like hydrocephalus) and male sex. The incidence of adverse outcome is more in meningitis caused by gram-negative organism than those by gram-positive organisms. Furthermore, adverse outcome depends on the causative organism as well. Hearing loss has been reported commonly in meningitis caused by *H. influenzae* and *S. pneumoniae*. The prognostic value of amplitude integrated EEG in neonatal meningitis has been studied. Low voltage background pattern, less frequent sleep wake cycling and frequent seizures predicted adverse outcome. Brain imaging, specifically MRI scan of the brain, can help us to identify the complications early and guides us to prevent the severity of adverse outcome.

### BOX 3 Possible outcomes following neonatal meningitis

#### Adverse clinical outcomes

- Seizure disorder
- Cerebral palsy
- Hydrocephalus
- Sensorineural hearing loss
- Cognitive and behavioral problems
- Vision impairment
- Speech and language disorders
- Global developmental delay.

## PREVENTION

Preventive strategies include intrapartum antibiotic prophylaxis, better infection control measures and earlier diagnosis and adequate treatment to improve the outcome. Intrapartum antibiotic prophylaxis for GBS-colonized women or those who have clinical risk factors for infection have effected a reduction of early onset GBS infection and therefore, meningitis in developed countries. However, this may or may not prevent early onset infection in India, as the causative organisms are different.

It is essential to prevent transmission using optimal hand-hygiene and better education of healthcare staff. It is also important to avoid catheter-induced infections by removing indwelling catheters such as the long lines and umbilical catheters as soon as possible. In order to prevent adverse outcome following neonatal meningitis, it is vital to diagnose it early and institute appropriate management.

## OTHER CAUSES OF NEONATAL MENINGITIS

### **Candida Meningitis/CNS infection**

The incidence of CNS involvement in candida infection is nearly 25%. *Candida albicans* is the most often observed spp with neonatal infection, but *Candida parapsilosis* is also seen in some NICUs. The increase in incidence of *Candida* in NICUs is attributed to interventions such as prolonged intubation, indwelling vascular devices, steroid therapy, parenteral nutrition, and frequent and prolonged use of broad-spectrum antibiotic therapy. The risk factors associated with fungal infections are mentioned in **Box 4**.

#### **BOX 4 Risk factors for candida infection in newborn infants**

- Preterm infants (less than 32 weeks gestation)
- Intrauterine growth restriction
- Prolonged umbilical or central vascular catheter use
- Total parenteral nutrition use
- Mechanical ventilation
- Prolonged antibiotic use
- Use of corticosteroids.

Candida infection of CNS is essentially the result of blood-stream infection. The clinical signs and symptoms are nonspecific, and similar to bacterial meningitis. Diagnosis of CNS involvement in candida infection is difficult as CSF analysis may be negative with normal CSF cell count and biochemistry. Candida isolation from CSF culture is suggestive of meningitis and never should be dismissed as contaminant. However, CSF culture may be sterile in cases of CNS infection without meningeal involvement. In these situations, diagnosis can be made when *Candida* spp is isolated from another sterile site such as blood and urine, or any organ involvement (like liver or renal abscess). MRI or CT brain may be necessary to diagnose cerebral abscess.

Amphotericin B, 5-flucytosine and fluconazole are the antimicrobials of choice for the treatment of candidiasis in NICU. It is generally recommended to use amphotericin B and 5-flucytosine as combination in candida meningitis. Liposomal preparations of amphotericin B penetrate the blood brain barrier to a greater extent than the conventional preparation. The optimal

duration of the antimicrobials is unknown, but recommended until sterilization of CSF occurs.

### **Viral Meningitis**

Viral meningitis in newborn infants is usually caused by enterovirus, Coxsackie B and echoviruses 4, 6, 9, and 11. In newborn infants, it can be difficult to distinguish clinically from bacterial meningitis as they have common nonspecific signs and symptoms. CSF analysis most often reveals normal levels of protein and glucose with pleocytosis. Enterovirus PCR in CSF has been recently used as a diagnostic tool with reported high sensitivity and specificity. Infants with viral meningitis will need only minimal supportive treatment for short duration. The outcome for viral meningitis is usually good.

### **IN A NUTSHELL**

1. Neonatal meningitis is associated with high case fatality and severe neurological sequelae.
2. Bacterial meningitis is the commonest etiology in newborns and causative organisms are not different for early and late onset disease.
3. Resistant gram-negative organisms and *Staphylococcus* are common causes of meningitis in hospital acquired infections.
4. The clinical features of meningitis are nonspecific and similar to that of sepsis.
5. In strongly suspected cases of sepsis, CSF examination should be done as a part of investigations.
6. Aggressive supportive treatment including temperature stability, ventilation and fluid resuscitation plays a key role in outcome.
7. Appropriate antibiotic treatment should be initiated as soon as possible.

## Chapter 15.4

# Deep-seated Infections

Kumutha Jayaraman, Manigandan Chandrasekaran

Deep-seated infections should be considered when an obvious reason or focus of illness could not be identified in a sick newborn infant. They include osteomyelitis, septic arthritis, urinary tract infection (UTI) and deep-seated abscesses. High index of suspicion is necessary for diagnosing these infections as they are not uncommon and there is paucity of signs and symptoms in the early stages.

### SEPTIC ARTHRITIS

Septic arthritis is defined as an inflammation of a synovial membrane with purulent effusion into the joint capsule, usually due to suppurative infectious arthritis. The incidence of septic arthritis is low, around 0.3 per 1,000 livebirths in western countries. The exact incidence in India is not available currently. In a tertiary out-born neonatal unit in South India, the incidence of septic arthritis was 16 per 1,000 neonatal admissions in 2013 (unpublished data). Early involvement of orthopedic team is necessary to avoid crippling sequelae. Septic arthritis can destroy the joint rapidly resulting in bony erosions and fibrous ankylosis. On occasions, the disease progression can extend and result in generalized sepsis.

### Etiology

*Staphylococcus aureus* is the most common causative organism for most cases of septic arthritis in neonatal period. Gram-negative bacilli such as *Klebsiella*, *E. coli*, *Enterobacter*, group B streptococci and *C. albicans* are also responsible for smaller percentage of cases (around 20%). Prematurity and low birthweight infants are particularly vulnerable to septic arthritis. Hip, knee and elbow are the most often affected joints in young infants but any joint can be affected.

### Pathogenesis

The joint may get infected by hematogenous spread, by direct extension from an adjacent area of osteomyelitis, or by direct inoculation of bacteria. Following bacterial invasion of the joint, there is an acute inflammatory response, which involves migration of polymorphonuclear cells, production of proteolytic enzymes and cytokine secretion by chondrocytes, with subsequent suppuration. The containment of suppuration within the joint, by virtue of thick anatomical barriers, results in increased intra-articular pressure and conditions for destruction of articular cartilage. Degradation of articular cartilage can begin as early as 8 hours of infection. Intracapsular synovial proliferation and an exudate or transudate of fluid, leads to stretching of the joint capsule causing laxity and possible subluxation or dislocation as a consequence.

### Clinical Features

Limitation in use of an extremity progressing to pseudoparalysis is characteristic of septic arthritis, and some infants do show external signs of inflammation (swelling, warmth or erythema), more localized to the affected joint. Evidence of pain with manipulation, such as lifting or diaper changing, is a common sign of bone infection. Newborn infant may show signs of discomfort like crying, on handling the affected joint. The growing preterm infant may present with failure to thrive. In around 20% of cases of septic arthritis, fever may be present.

### Diagnosis

Ultrasound examination of the joint will identify a joint effusion (Figs 1A and B), but the presence of echogenic debris may be more suggestive of infection (Box 1). Plain X-rays in septic arthritis of the hip may be helpful, demonstrating lateral displacement of the hip or dislocation (Figs 1A and B), but may also be entirely normal (Box 2). Abnormal radiological features usually appear late. In septic arthritis, raised white blood cell count, elevated C-reactive protein, and a falling platelet count are often observed. Bone scintigraphy and MR imaging may be needed in those infants suspected of osteomyelitis since normal results at US does not exclude osteomyelitis. Technetium bone scans are helpful when the focus of infection cannot be localized. It is highly sensitive but less specific. MRI scan is highly sensitive and specific for septic arthritis. Delay in diagnosis and treatment results in joint destruction with secondary osteoarthritis or ankylosis, growth plate arrest, dislocation, and avascular necrosis.

**Figures 1A and B** USG (A) and X-ray (B) of shoulder joint with features of septic arthritis. USG shows collection of hyperechoic fluid (as indicated by arrow) in joint space. X-ray reveals joint space widening, soft tissue swelling and lytic lesion in proximal humerus (as indicated by arrow)

#### BOX 1 Ultrasound features of septic arthritis in a newborn infant

- Joint effusion—hyperechoic fluid
- Thickening and elevation of joint capsule
- Synovial hypertrophy
- Adjacent intramuscular collection
- Displacement or dislocation of the joint.

#### BOX 2 X-ray features of septic arthritis

- Soft tissue swelling around the joint
- Widened joint space—because of effusion
- Displacement of adjacent fat pads
- Loss of visualization of white cortical line due to bone destruction marginal erosions
- Features of osteomyelitis including periosteal reaction, bone destruction, sequestrum formation
- Narrow joint space as articular cartilage is destroyed in later stages
- Displacement or dislocation of the joint.

### Treatment

**Antibiotic therapy** This should be started as soon as the diagnosis is suspected. The combination of IV vancomycin and cefotaxime should cover most organisms. Suggested antibiotic therapy is

mentioned in **Table 1**. The recommended duration of antibiotics is 4 weeks (with initial 2 weeks as IV antibiotics), however, it may be increased to 6 weeks depending on coexisting osteomyelitis.

**Surgical management** Removal of pus and inflammatory debris from the joint is an essential component of the management of septic arthritis. Aspiration of the joint is mandatory and should be performed under ultrasound guidance. When conservative treatment fails or in cases of associated osteomyelitis, arthrotomy should be performed. Immobilization of the affected joint is necessary with the splints, as long as the antibiotic therapy is given.

**Table 1** Suggested antibiotics and their dosage in septic arthritis

Gram stain	Antibiotics	Dose
Gram-positive cocci ( <i>Staphylococcus aureus</i> , Group B <i>Streptococcus</i> )	Cloxacillin	25–50 mg/kg 8 hourly
	Vancomycin	15 mg/kg 8 hourly
Gram-negative bacilli ( <i>E. coli</i> , <i>Klebsiella</i> )	Cefotaxime	50 mg/kg 8 hourly after first week of life (12 hourly in the first week of life)
	Amikacin	15 mg/kg 24 hourly
	Meropenem	20 mg/kg 12 hourly
	Piperacillin/tazobactam	90 mg/kg 8 hourly
Gram-negative cocci (meningococci, pneumococci)	Ceftazidime	25 mg/kg 24 hourly in the first week of life (12 hourly after 1 week of age)
	Ceftriaxone	50 mg/kg 24 hourly
	Piperacillin/tazobactam	90 mg/kg 8 hourly

## Prognosis

Untreated hip joint infection can result in vascular compromise and ischemic necrosis of the femoral head (**Box 3**). Early diagnosis and timely treatment can result in good outcome.

### BOX 3 Complications of septic arthritis of the hip joint

- Chondrolysis
- Avascular necrosis femoral head/neck
- Pseudarthrosis of femoral neck
- Premature closure of proximal femoral physis
- Premature closure triradiate cartilage
- Overgrowth of greater trochanter
- Dislocation of the joint.

## OSTEOMYELITIS

Osteomyelitis is relatively uncommon in a newborn infant. Incidence rates have been reported between 0.12 and 0.66 per 1,000 livebirths in western countries.

## Etiology

*Staphylococcus aureus*, *Klebsiella* and *E.coli* are frequent causes of osteomyelitis. Group B *Streptococcus*, coagulase-negative staphylococci, *Enterobacter cloacae*, and *Citrobacter freundii* are infrequent causes, particularly in extremely preterm neonates. Case reports of bone infections caused by *Mycoplasma hominis* and *Ureaplasma urealyticum* have also been reported.

## Pathogenesis

Osteomyelitis is often due to bacteremia; the spread of infection is via hematogenous route. Hence, factors that predispose to bacteremia have been recognized as risk factors for osteomyelitis

(**Box 4**). In preterm infants, umbilical catheterization is associated with a higher incidence of osteomyelitis. Catheterization of other blood vessels, particularly femoral vessels, has also shown to be a risk factor. Septic emboli may form in vascular catheters, acting as a focus for bacteremia and hence, infection.

### BOX 4 Risk factors for neonatal osteomyelitis

- Prematurity
- Birthweight less than 1,500 g
- Total parenteral nutrition
- Invasive procedures like umbilical catheterization.

Long bones are commonly affected in osteomyelitis, particularly femur, tibia and humerus. Most infections are localized to the metaphysis of long bones. This predilection to metaphysis is due to the specific pattern of developing blood vessels near the ends of the bone. The blood flow, near the end of the bone, is sluggish as the arterioles end in venous sinusoids by turning abruptly. Bacteria in the circulating blood get trapped in these areas, accumulate and multiply rapidly which leads to an infection. Furthermore, the lining of the venous sinusoids contains no phagocytic cells. Once infection sets in, inflammatory pathways are triggered, which involves migration of polymorphonuclear cells, production of proteolytic enzymes and cytokine secretion, leading to abscess formation. If not diagnosed and treated at this stage, this infection can spread and eventually lead to periosteal abscess and septic arthritis. In around 70% of cases, the adjacent joint is involved, as the infected metaphysis is intracapsular.

## Clinical Features

In newborn infants, there is often very little systemic response. Hence, many infants remain afebrile and do not appear particularly ill in early stages of infection. Later, the infant begins to develop subtle signs such as nonspecific irritability or poor handling during routine care. Subsequently, established clinical signs such as swelling of the involved limb, local erythema, and more specifically, absence of movement in the affected limb, termed as *pseudoparalysis* are observed (**Box 5**). Sometimes, osteomyelitis in neonates can present as a severe disease similar to a septic newborn and the newborn baby will be sick in those situations. Affected babies may have extreme irritability, lethargy and metabolic acidosis. The babies may have multiple subcutaneous abscesses. They may have cardiovascular and respiratory compromise, presenting in septic shock. In chronic cases of osteomyelitis, bony induration could be felt in the affected area.

### BOX 5 Clinical features of neonatal osteomyelitis

- Irritability
- Persistent crying
- Swelling of the limb
- Subcutaneous swelling due to periosteal abscess
- Local erythema
- Pseudoparalysis—absence of movement of the affected limb.

## Diagnosis

The first abnormality on the plain X-ray is swelling of the soft tissues surround the bony site of infection. This appears in around 3 days after the onset of infection. Signs of bone destruction may be observed in 7 days after the onset of infection. Articular swelling and widening of joint space may be seen in neighboring joint. Bones may evolve to have multiple areas of rarefaction later. As the bone begin to remodel soon, signs including periosteal reaction due to production of thin layer may appear around 2 weeks after

the infection. Ultrasonography may be useful to identify abscess and the site for drainage. Blood cultures are positive in around 50% of infants with osteomyelitis.

### Treatment

The main treatment for osteomyelitis is appropriate parenteral antimicrobial therapy. This should be ideally started after obtaining blood cultures. The combination of cefotaxime and vancomycin is reasonable to start until the specific organism is identified through cultures. When the clinical and/or inflammatory marker response is not observed after starting the initial antibiotics or the clinical condition deteriorates, next line antibiotics should be considered. Carbapenems such as meropenem and imipenem, possess the widest range of activity against gram-positive and gram-negative bacteria. The safety and efficacy of meropenem is similar to that of third generation cephalosporins. Linezolid, tigecycline, and daptomycin should also be considered. Tigecycline, a glycylglycyl antibiotic, is active against many gram-positive and gram-negative bacteria. Aztreonam (for gram-negative organisms) and linezolid (for gram-positive organisms) are emerging antibiotics that have shown positive results in neonatal infections. The total duration of antibiotic therapy should be 6 weeks and the entire course should be administered intravenously. It is also required to immobilize the affected limb in order to help the healing process.

### Long-term Outcome

Neonatal osteomyelitis may affect the growth plate, leading to impaired growth of the affected limb shortening. The final outcome may be apparent only in later life. When neighboring hip joint is involved in osteomyelitis involving femur, it may lead to avascular necrosis of the femoral head. In addition, it may eventually develop degenerative arthritis in the affected joint. Rapid decompression of the infected joint is necessary to have a best outcome in these situations.

## URINARY TRACT INFECTIONS

The incidence of UTI in newborn infants varies from 0.1% to 1%. It is more common in male than female infants in the first 3 months of age. It is also more common in preterm and low birthweight infants; high incidence of up to 20% has been reported in literature. UTI is more commonly associated with late onset sepsis than early onset sepsis. UTI may be asymptomatic in newborn infants, but should be diagnosed and treated promptly as it may result in long-term complications. In around 30–50% of infants with UTI, congenital urinary tract anomalies are concomitant. Hence, it is important to evaluate infants with proven UTI in detailed and appropriate manner.

### Etiology

The commonest pathogen, causing UTI in newborn infants, is *E. coli*. The virulence determinants of uropathogenic *E. coli* have been most studied comprehensively. The most consistent of those factors include adhesins, P fimbriae, cytolysins and hemolysins. Adhesins are specifically important determinants because the initial event in the pathogenesis of UTI is the adherence of *E. coli* to the urogenital mucosa by infecting *E. coli*, an event mediated by adhesins. P fimbriae appear to be especially important in *E. coli* pyelonephritis. Several studies have consistently demonstrated that these adhesins are present in nearly 100% of strains causing pyelonephritis. In addition, Gram-negative enteric bacteria such as *Klebsiella pneumoniae*, *Pseudomonas* spp., *Enterobacter* spp., and some Gram-positive cocci, including coagulase-negative staphylococci, *Staphylococcus aureus* and enterococci, can cause neonatal UTI.

*Candida* spp., has also been shown to be an important causative factor for UTI, particularly in preterm and low birthweight infants who are hospitalized for long duration.

### Pathophysiology

The pathophysiology of UTI characterizes an altered balance between host and pathogen. The abnormal anatomy of the urinary tract aids to aggravate the effects of UTI. Most UTIs start in the bladder and then ascend to produce pyelonephritis. Once bacteria are in the renal parenchyma, focal infection and inflammation develop, and the inflammatory cascade occurs. If this process is not interrupted by treatment, it can produce severe renal injury or scarring. Furthermore, if repeated infectious insults such as these continue without adequate therapy, the long-term result is significant renal scarring. Some infants are more susceptible to bacterial UTIs because their bladder mucosa expresses cell surface proteins that have a high affinity for cell surface antigens on the bacterial cell wall.

### Clinical Features

The symptoms and signs of UTI in newborn are usually generalized rather than specific for UTI. Infants usually present with lethargy, poor feeding, poor weight gain and jaundice. In one study from Iran, UTI was found in around 6% of infants with late onset jaundice. Newborn infants may also present acutely with all the signs of sepsis. Poor weight gain and low grade fever has also been reported with newborn infants with UTI. On clinical examination, signs relevant to the diagnosis of UTI include renal mass due to hydronephrosis or other congenital abnormality, and enlarged bladder suggesting outflow obstruction. Genitalia examination should be done in newborn infants with UTI to rule out urogenital anomalies including phimosis. History should be elicited about the stream of the urine in male infants to rule out posterior urethral valve.

### Diagnosis

High index of suspicion is necessary as the symptoms are nonspecific. In cases of infants with late onset sepsis, or aforementioned symptoms with no focus of infection, collection of urine specimen for analysis and culture must be included in the evaluation. Suprapubic aspiration is the widely recommended method for collecting urine. A urine culture should be repeated in case contamination is suspected, for example, mixed growth of two or more pathogens, or growth of organisms that normally constitute the periurethral flora (enterococci in infants). The culture should also be repeated in situations where UTI is strongly suspected but colony counts are low or equivocal. The number of bacteria required for defining UTI depends on the method of urine collection, as mentioned in **Table 2**.

### Further Investigations

Once a diagnosis of UTI has been proven, it is vital to initiate a radiographic workup [ultrasound study of kidneys and bladder, followed by micturating cystourethrogram (MCU)] to look for any

**Table 2** Criteria for diagnosis of UTI (as recommended by Indian Society of Pediatric Nephrology)

Method of collection	Colony count	Probability of infection
Suprapubic aspiration	Any number of pathogens	99%
Urethral catheterization	$> 5 \times 10^4$ CFU/mL	95%
Clean catch midstream	$> 10^5$ CFU/mL	90–95%

underlying structural anomalies. Around 30–50% of infants with a UTI have aberrant urinary tract anatomy. The most common anatomic abnormality associated with a febrile UTI in a neonate or infant is vesicoureteral reflux (VUR). Typically, a 2- to 4-week period has been recommended between the infection and the MCU. It is more important to ensure that the urine is sterile before performance of the MCU. The infant should be maintained on antimicrobial prophylaxis until imaging rules out any urinary tract pathology.

An important consideration is what happens when UTIs develop in a newborn with an abnormal urinary tract. With the use of prenatal sonography, most of the newborns with an obstructive uropathy are identified at birth, and antibiotic prophylaxis is initiated. However, some newborns may still present with urosepsis and obstructive uropathy gets detected only in the postnatal period. In such cases, the obstructive uropathy might have developed after the initial early normal prenatal ultrasound examination, or the problem went undiscovered because of a lack of access to prenatal care.

### Treatment

All neonatal infants with UTI should be hospitalized and treated with parenteral antibiotics. The choice of antibiotic should be guided by local sensitivity patterns. A guide to antibiotic therapy is provided in **Table 3**. Once the result of antimicrobial sensitivity is available, the treatment may be modified. The duration of antibiotic therapy should be 2 weeks. Intravenous therapy is given for the entire duration of antibiotic therapy. During an episode of UTI, it is important to maintain adequate hydration. Routine alkalization of the urine is not necessary. Paracetamol is used to relieve fever; therapy with nonsteroidal anti-inflammatory agents should be avoided. A repeat urine culture is not necessary, unless there is persistence of fever and toxicity despite 72 hours of adequate antibiotic therapy.

Sometimes, an obstructed system may be noticed during the investigations. The management may be different in these cases as the use of surgical drainage by either ureterostomy or percutaneous nephrostomy. During treatment if the newborn infant does not defervesce within 72 hours or clinical condition worsens underlying obstruction must be suspected. Under these circumstances, an ultrasound examination to rule out obstruction is warranted.

**Table 3** A guide to antibiotic therapy in newborn infants with UTI

First line	Ampicillin	50 mg/kg 8 hourly (75 mg/kg 6 hourly in infants more than 7 days old)
	Gentamicin	4 mg/kg 24 hourly
	Amikacin	15 mg/kg 24 hourly
Second line (In infants older than 7 days of age)	Cefotaxime	100 mg/kg 12 hourly (8 hourly in infants more than 7 days old)
Second line (In cases of hospital onset infections)	Vancomycin	15 mg/kg 12 hourly (8 hourly in infants more than 7 days old)
Third line	Meropenem	20 mg/kg 12 hourly (8 hourly in infants more than 7 days old)

### Long-term, Low Dose, Antibacterial Prophylaxis

It is used to prevent recurrent UTI. The antibiotic used should be effective, non-toxic with few side effects and should not alter the growth of commensals or induce bacterial resistance. The recommended antibiotic for prophylaxis in newborn infants and in first 3 months of age is co-trimoxazole [sulfamethoxazole and trimethoprim (2 mg/kg)] once a day. Some prefer amoxicillin (15–20 mg/kg once a day) as a first choice. Cephalexin (10 mg/kg/day) and cefadroxil (5 mg/kg/day) may be used as alternatives.

The indications and duration of prophylaxis depend on patient age and presence or absence of VUR. Antibiotic prophylaxis is recommended for patients with (i) UTI below 1-year of age, while awaiting imaging studies, (ii) presence of VUR, (iii) frequent febrile UTI (three or more episodes in a year) even if the urinary tract is normal. For grades 1 and 2 of VUR, antibiotic prophylaxis should be given until 1 year of age. For grades 3, 4 and 5, it should be given until 5 years of age, and also surgery should be considered in these grades if breakthrough febrile UTI occurs.

Breakthrough UTI results either from poor compliance or associated voiding dysfunction. The UTI should be treated with appropriate antibiotics. A change of the medication being used for prophylaxis is usually not necessary.

### Long-term Outcome

Infants with a renal scar (reflux nephropathy) should be counseled regarding the importance of early diagnosis and treatment of UTI and regular follow-up. Physical growth and blood pressure should be monitored every 6–12 months, through adolescence. Investigations include urinalysis for proteinuria and estimation of blood levels of creatinine. Annual ultrasound examinations are done to monitor renal growth.

### IN A NUTSHELL

1. Septic arthritis is a medical emergency that requires rapid diagnosis and treatment to avoid morbidity and mortality.
2. *S. aureus* is the most frequent causative pathogen for septic arthritis and osteomyelitis.
3. Hip is the common site for septic arthritis, while long bones are commonly affected in osteomyelitis.
4. Urinary tract infections in newborn infants should be preferably confirmed by suprapubic bladder puncture.
5. Parenteral antibiotics should be given in suspected pyelonephritis for total duration of 2 weeks.
6. Infants with UTI should be evaluated for the presence of complications, underlying anomalies or voiding dysfunction.
7. Renal ultrasound as first-line imaging in neonatal UTI, together with clinical criteria and laboratory parameters (raised inflammatory markers) determine further risk-oriented diagnostic imaging strategies (i.e., MCU).
8. Long-term antibacterial prophylaxis should be initiated in infants with urethral valves, high-grade vesicoureteral reflux, and obstructive megaureter.

## Chapter 15.5

# Neonatal Tetanus

Mala Kumar, Shalini Tripathi

Neonatal tetanus (NT) is an acute neurological illness occurring in the first 28 days of life. It is the second most important cause of infant mortality among the six vaccine preventable infections in developing countries. It has been largely eliminated from developed countries as a result of maternal immunization during pregnancy. However, it is still rampant in developing countries especially in Asia and Africa. In 1989, the World Health Assembly community had pledged to eliminate (incidence of less than one case per 1,000 livebirths) NT by 1995 but could not do so. In 1999, a new target date for elimination of NT was set by 2005. However, in December 2013, only 34 of 59 countries in the world had achieved maternal and NT elimination leaving 25 countries that still had not eliminated the disease.

Neonatal tetanus has been eliminated in 15 states of India in 2008. According to World Health Organization in 2011, 734 cases of NT were reported in India. Maximum numbers of cases were from West Bengal, Assam and Odisha. However, the disease is under reported. True NT burden is likely to be substantially higher than the reported numbers as many of the neonates are born at home and die there. NT has marked seasonal incidence in India. More than 50% of the total annual cases occur in the months of July, August and September.

## ETIOLOGY AND PATHOGENESIS

The causative organism for NT is *Clostridium tetani*, which is a Gram-positive obligate noninvasive anaerobic bacillus. It looks like a racquet and bears spores. These spores are very robust and are resistant to disinfectants and to boiling. They can be destroyed by autoclaving at 120°C for 20 minutes or prolonged exposure to iodine, formalin or glutaraldehyde or by gamma irradiation. The spores are abundant in the soil and animal and human feces.

They germinate in sites with a low oxidation reduction potential like in necrotic tissue. The vegetative form is destroyed by disinfectants, boiling and antibiotics. The vegetative form produces a very potent inactive neuron-specific toxin (tetanospasmin). Tetanus toxin is very potent toxin second to only botulism toxin. Its minimum lethal dose is 2.5 ng/kg in humans. The genes for the neurotoxin and its transcriptional regulator, ToxR are located in an intracellular plasmid. At autolysis, after the death of the bacterium, the toxin is released and transformed by proteases into its active form: a 100 kDa heavy chain and 50 kDa light chain. After release tetanus toxin diffuses into the adjacent muscle tissue and binds to specific glycoproteins of the plasma membrane of the alpha motor neurons and is absorbed by endocytosis. The toxin then travels by a retrograde axonal transport system and at the spinal cord and brain-stem level diffuses across synaptic spaces to enter glycinergic and gabaergic inhibitory interneurons. It then crosses the synapse to enter the presynaptic neuron and inhibits the release of inhibitory transmitters: glycine and gamma-aminobutyric acid (GABA) from vesicles. The action of the inhibitory neurons is impeded leaving alpha motor neuron excitation unopposed. This causes uninhibited firing of the motor neurons causing rigidity. There is simultaneous contraction of agonists and antagonists causing painful spasms. In addition, the toxin can have a profound effect on the autonomic nervous system causing a hyperadrenergic state. The effect of the toxin persists for weeks.

## CLINICAL FEATURES

The clinical picture of a neonate with tetanus is remarkable. The neonate is born to an unimmunized or partially immunized mother and the cord has been cut unhygienically. The incubation period, i.e., the period between the introduction of spores of tetanus and the first symptoms of disease is 3–21 days. Most neonates have the first symptom after day 2 of life but within the first 2 weeks in the form of failure to suck. This is accompanied by excessive crying, irritability and fever. This is followed by appearance of the pathognomonic signs of *trismus* (lockjaw) and *risus sardonicus* (facial rigidity). In severe cases, generalized muscular spasms which are typically stimulated by touch, noise or bright light follow. The spasms are painful and the neonate remains fully conscious throughout the illness. The neonate may assume the posture of opisthotonus and may develop respiratory arrest. As a rule, NT follows a descending pattern of nerve involvement. The first sign is trismus followed by difficulty in swallowing, stiffness of neck and rigidity of abdominal muscles especially on touch. The period between the first symptom and the first spasm is known as the period of onset. The shorter this period, the more severe is the disease. Autonomic dysfunction may be evident with the development of hypertension, hypotension, diaphoresis and arrhythmias. Recovery begins after 3 weeks and occurs over a period of about 4 weeks. In half of the neonates with tetanus omphalitis is not evident.

## Complications

The complications of NT include laryngospasm, hyperactivity of autonomic nervous system, fracture of long bones and spine, aspiration pneumonia (a common late complication), coma, and death—mostly occurs in the first week of disease.

## DIAGNOSIS

Diagnosis is essentially clinical. The typical setting is a neonate born to an unimmunized mother at home with unhygienic cord care with typical symptomatology. Cultures from the umbilical stump usually grow no organisms and are of no use in making a diagnosis. A confirmed case of NT is defined as a child with history of all three of the following:

1. Normal feeding and crying during the first 2 days of life
2. Onset of illness between day 3 and 28 of life
3. Inability to suckle (trismus) followed by stiffness (generalized muscle rigidity) and or convulsions (muscle spasms).

## DIFFERENTIAL DIAGNOSIS

### Meningitis

This may be associated with bulging fontanel along with other features of neonatal sepsis like refusal to feed, hypothermia but trismus is not present.

### Hypocalcemia

It presents in either first 2–3 days (early onset) or end of the first week-beginning of the second week (late onset). There is no trismus; infant appears normal between episodes of seizures and there are no spasms on touch. Serum calcium is low.

## MANAGEMENT

### Supportive Care

The neonate should be nursed in a dark, quiet room with minimal stimuli and facility for mechanical ventilation. The patient should be kept nil oral initially and given IV fluids. Endotracheal

intubation should be done to prevent aspiration of secretions before laryngospasm develops. Since endotracheal intubation may provoke spasms and seizures, early tracheostomy may be required.

### Neutralization of Unbound Tetanus Toxin

As soon as the diagnosis of tetanus is made and neonate is adequately sedated, single dose of human tetanus immunoglobulin [tetanus immune globulin (TIG) produced by Serum Institute of Pune] should be given intramuscularly. The dose of TIG is still undetermined. Single dose of 500 units usually suffices but dose as high as 3,000–6,000 units may be given. Infiltration of TIG into the wound and intrathecal administration to neutralize toxin in the spinal cord, is not recommended. If human TIG is not available equine antitoxin (1,500–3,000 unit) can be given intravenously or intramuscularly after sensitivity testing (0.1 mL intradermal injection in a 1:10 dilution). Pooled intravenous immunoglobulin also contains 4–90 U/mL of TIG, but the dose of IVIG for treating NT is not known.

### Antimicrobial Therapy

Conventionally Penicillin G in a dose of 100,000 units/kg/day IV divided every 4–6 hourly for 10–14 days is the antibiotic of choice. Metronidazole (30 mg/kg/day) divided 6 hourly is equal or better than Penicillin G as Penicillin G is a GABA antagonist just like tetanus toxin.

### Treatment of Muscle Spasms

First priority in NT should be to decrease muscle spasm. Benzodiazepines with or without neuromuscular blocking agents are the mainstay of symptomatic therapy for NT. Benzodiazepines are GABA agonists and thereby antagonize the effects of the toxin. Diazepam is proved to be effective in decreasing spasms without depression of cortical centers. It is started at a dose of 0.1–0.2 mg/kg/dose every 3–6 hourly. If spasms are not controlled, then can be increased to 0.4–0.6 mg/kg/dose. High dose diazepam can also be given in a dose of 10–40 mg/kg/day as IV infusion. The presence of a ventilator as a backup is a must while using high doses of diazepam. The propylene glycol present in the injectable preparation of diazepam may cause lactic acidosis, which should be monitored. Diazepam is continued over 2–6 weeks with gradual withdrawal as sudden withdrawal may cause withdrawal reaction. Gradual withdrawal is done by decreasing 10% of its dose every third day. Midazolam is given in a dose of 0.05–0.15 mg/kg/dose slowly IV over more than 15 minutes (with a final infusion concentration of 0.5 mg/mL of normal saline or dextrose); it can be repeated after 2–4 hours or be given as a continuous infusion in a dose of 0.1–0.2 µg/kg/minute. Lorazepam can also be given in a dose of 0.05–0.1 mg/kg/dose IV over more than 5 minutes. It can be repeated after 10–15 minutes if necessary. Midazolam has the advantage of not having propylene glycol, thus avoiding lactic acidosis.

If the muscle spasms are not adequately controlled by benzodiazepines or threaten ventilation due to laryngospasm or respiratory muscle spasm, neuromuscular blocking agents like vecuronium/pancuronium can be used along with mechanical ventilation. Patient should be monitored meticulously while on these drugs and the drugs must be stopped once a day to assess the patient's condition. Vecuronium (0.1 mg/kg/dose, range 0.03–0.15 mg/kg/dose; IV push; q 1–2 hour as needed), has less cardiovascular side effects than pancuronium (0.1 mg/kg/dose, range 0.05–0.15 mg/kg/dose, slow IV push; q 1–2 hour as needed). Pancuronium can increase the autonomic instability by inhibiting catecholamine reuptake and causes tachycardia.

Other agents which can be used to control muscle spasm are meprobamate, phenobarbitone, chlorpromazine, dantrolene

and baclofen. Intrathecal baclofen has been proved promising in children but there are no data available in neonates. Pyridoxine (100 mg/day) in addition to the conventional treatment has been found to decrease mortality and spasm in neonatal studies but large studies are not available.

For autonomic dysfunction alpha and beta blocker—labetalol or magnesium sulfate can be used. Magnesium sulfate acts by blocking peripheral neuromuscular transmission and by decreasing the release of acetylcholine at motor end plate by motor nerve impulse. It also reduces catecholamine release from adrenal medulla and receptor responsiveness to released catecholamines. It is given by IV loading 75 mg/kg then continuous infusion at a rate of 20–50 mg/kg/hour. Magnesium levels need to be monitored as it can cause muscle paralysis by antagonizing calcium metabolism. Labetalol is given as a continuous infusion in a dose of 0.4–1 mg/kg/hour not exceeding 3 mg/kg/hour. Hypotension if present, is treated by fluid administration, dopamine and norepinephrine infusion.

### PROGNOSIS

Onset of symptoms within the first week of life, a short period of onset, high fever, tachycardia and severe spasms resulting in apnea are predictors of a poor prognosis. The most important factor affecting outcome is the kind of supportive care given. Mortality is 75% without treatment and less than 10% with wholehearted management. The cause of death is aspiration pneumonia or anoxia due to spasms. About 10–30% of survivors demonstrate neurological sequel in the form of mental retardation and spastic motor deficits due to hypoxic ischemic injury due to severe muscle spasms and respiratory compromise.

### PREVENTION

Recovery from tetanus does not result in toxoid neutralizing antibodies, so patient has to be actively immunized after recovery. Infants born to immune mothers acquire temporary immunity for about 5 months. However, if an infant is born less than 15 days after the mother's second dose of TT, the infant will not be protected. A significant level of immunity in mothers can be achieved by two doses of TT at least four weeks apart. In addition, ensuring hygiene during delivery and in cord care can be effective in preventing NT.

#### IN A NUTSHELL

1. Neonatal tetanus is a vaccine-preventable disease that can be eliminated by maternal immunization.
2. Trismus is a pathognomonic feature of NT.
3. Antimicrobial treatment, tetanus immunoglobulin, diazepam and respiratory support can reduce mortality.
4. Early intubation/tracheostomy reduces mortality.
5. Superadded bacterial pneumonia may contribute to mortality.
6. Clinical disease does not confer long lasting immunity on the infant and, therefore, active immunization with diphtheria starting at 6 weeks is a must.

## Chapter 15.6

# Intrauterine Infections

Sriparna Basu, Ashok Kumar

Congenital infections are defined as those infections which are acquired through transplacental entry of organisms from maternal bloodstream into the fetus, or transmitted during passage through the birth canal. Maternal illness is usually mild and sometimes even unnoticed; however, the impact on the developing fetus may be severe enough to cause fetal loss or congenital malformation. Chronic postnatal infection with development of sequelae in later life may also be seen in some cases. Severity of manifestation depends on the gestational age of the fetus at the time of infection, virulence of the organism, extent of damage to the placenta, and the nature of maternal infection (primary versus reinfection).

## NOMENCLATURE

The first documented congenital infection is Rubella embryopathy. It was discovered by the Australian ophthalmologist Sir Norman Gregg in 1941. The acronym *TORCH* was proposed by Andres Nahmias in 1971 to include four congenital infections (*T*Oxoplasmosis, *R*ubella, *C*ytomegalovirus and *H*erpes simplex) which were at times difficult to differentiate. In 1975 Harold Fuerst proposed a new acronym *STORCH* which included Syphilis, *T*oxoplasmosis, *O*ther (Varicella zoster, Parvovirus) *R*ubella, *C*ytomegalovirus and *H*erpes simplex. Later on, to expand the list, even a bigger acronym *CHEAP TORCHES* was suggested. It included Chicken pox, Hepatitis, Enterovirus, HIV and Parvovirus. The list of Other infections continues to grow even today with identification of new etiologies and resurgence of several others. A complete list of infections is given in **Box 1**. Important congenital infections are discussed below.

### BOX 1 Intrauterine infections that can affect fetus or infant

#### Viruses

- Cytomegalovirus
- Rubella
- Herpes simplex virus
- Varicella zoster virus
- Hepatitis B and C
- Human immunodeficiency virus
- Parvovirus B19
- Measles virus
- Mumps virus
- West Nile virus
- Adenovirus
- Influenza virus
- Enteroviruses—coxsackie, echo
- Lymphocytic choriomeningitis virus
- Papilloma virus

#### Bacteria

- *Treponema pallidum*
- Group B *Streptococcus*
- *E. coli* and other gram-negative bacteria
- *Mycobacterium tuberculosis*
- *Listeria monocytogenes*
- *Salmonella*
- *Campylobacter*
- *Borrelia burgdorferi*

#### Parasites

- *Toxoplasma gondii*
- *Plasmodium* spp
- *Trypanosoma cruzi*

#### Fungi

- *Candida albicans*

## CYTOMEGALOVIRUS

Cytomegalovirus (CMV) is the largest and most complex member of the herpes virus family infecting humans. It is the most common congenital infection, the leading cause of mental retardation from viral etiology and the most frequent nonhereditary cause of sensorineural hearing loss (SNHL) worldwide. The prevalence of congenital CMV infection varies from 0.2% to 2% (average 0.65%) in developed countries. In developing countries, the reported prevalence varies substantially, both within and among different countries. Several authors have reported prevalence as high as 6–14%.

## Transmission

Cytomegalovirus is a ubiquitous infection and spreads by close contact through saliva, blood, genital secretions, urine or breastmilk. Neonatal infection commonly occurs by three routes of transmission—intrauterine or transplacental, intrapartum, and postnatal (through breastmilk). It is estimated that 1–4% of CMV seronegative mothers become infected during pregnancy, and 30–40% of them transmit virus to the fetus. Most CMV infections during pregnancy are asymptomatic even during the acute stage of the disease. It has been reported that less than 5% of pregnant women with primary infection are symptomatic, and even a smaller percentage suffers from mononucleosis syndrome. The likelihood of fetal transmission and symptomatic disease is much higher during primary maternal infection (5–15%). Most children born to mothers with secondary CMV infection are asymptomatic at birth, and less than 10% of them develop postnatal sequelae.

Breastfeeding infants of CMV-seropositive mothers have an estimated rate of infection between 39% and 59%. The risk is higher at maternal viral load more than  $7 \times 10^3$  genome equivalents/mL. Excretion of the virus in breastmilk is maximum between 2 weeks and 2 months postpartum.

## Pathogenesis

Acute CMV infection leads to lytic virus replication, enlargement of cells with intranuclear inclusions, end-organ damage and ultimately virus-mediated cell death. Characteristic changes are seen in brain, liver, placenta and most of the other infected organs. Host inflammatory response targeting virus-infected cells may also lead to cellular damage. Factors contributing to fetal damage include gestational age of the fetus at the time of infection, immune status of the mother, extent of placental injury, viral load in the amniotic fluid, genotype of the infecting CMV strain along with fetal and placental genetic induction in response to infection and the effects of these induced genes.

## Clinical Manifestations

Symptoms and long-term neurodevelopmental sequelae are seen in 11–12.7% of congenital CMV infection. Clinical features seen in symptomatic CMV infection have been summarized in **Box 2**. SNHL is most commonly seen when CMV infection occurs in the first or second trimester. It is usually progressive, unilateral or bilateral, may even be absent at birth manifesting later in life. Incidence of CMV-induced hearing loss at birth has been recorded as 21% and 25% at 4 years of age. High incidence of mortality (about 30%) has been documented in severely affected infants. Most often deaths are secondary to hepatic dysfunction, bleeding, disseminated intravascular coagulation or superadded bacterial infections.

The important laboratory changes that may be seen include elevated alanine aminotransferase, thrombocytopenia, conjugated hyperbilirubinemia, evidence of hemolysis and elevated cerebrospinal fluid (CSF) protein.

**BOX 2 Clinical features of congenital cytomegalovirus infection**

- **Central nervous system:** Microcephaly, lethargy/hypotonia, lissencephaly with thinning of cortex, migrational abnormalities, polymicrogyria, schizencephaly, cerebellar hypoplasia, ventriculomegaly, periventricular calcification, delayed myelination, dysmyelination and white matter disease, periventricular cysts, seizure disorders, including infantile spasm
- **Ears:** Sensorineural hearing loss
- **Eyes:** Chorioretinitis, optic atrophy, cortical visual impairment, strabismus
- **Skin:** Petechiae, purpura, blueberry-muffin rash
- Prematurity/small for gestational age
- Jaundice, hepatitis
- Hepatosplenomegaly
- Pneumonia
- Hydrops
- Hypoplasia and hypocalcification of tooth enamel

**Diagnosis****Antibody Titers**

They are not reliable markers of fetal infection as maternal CMV IgG may cross the placenta, and only 20–70% of infected infants mount a weak IgM response.

**Viral Detection**

Viral detection in neonatal body fluids, such as urine, blood and saliva, by polymerase chain reaction (PCR), culture or antigen testing (pp65 antigen) within first 3 weeks of life may be done, which differentiates congenital infection from postnatal transmission. Saliva and urine samples are preferred as high levels of viruses are present in these fluids.

**Neurodiagnostic Imaging**

Cranial ultrasound is a good screening test in neonatal period though MRI of brain may be more definitive for symptomatic/affected infants.

**Other Investigations**

Ophthalmological evaluation for chorioretinitis and audiological evaluation by auditory evoked response to provide supportive evidence in symptomatic newborns.

**Treatment**

Currently, four drugs (ganciclovir, valganciclovir, cidofovir and foscarnet) have been licensed for the treatment of symptomatic congenital CMV disease involving central nervous system (CNS). Fomivirsen is also licensed for intravitreal administration to treat CMV-induced retinitis in patients with acquired immunodeficiency syndrome (AIDS). Of these drugs, only ganciclovir has been approved for treatment of neonates. Ganciclovir is administered in a dose of 12 mg/kg/day, by intravenous infusion in two divided doses for 6 weeks. All infected children should be closely monitored and followed-up at 1, 3, 6 and 12 months and then annually until school age. Monitoring includes physical, neurological and neurodevelopmental evaluation.

**RUBELLA**

Rubella is a single-stranded RNA virus, a member of the family *Togavirus*, and the genus, *Rubivirus*. In unimmunized populations, 10–20% women of reproductive age group are susceptible to rubella infection. Each year worldwide, an estimated 238,000 children are born with congenital rubella syndrome (CRS); most of these births take place in developing countries. Incidence of congenital infection in association with maternal reinfection is rare.

**Transmission**

During pregnancy, rubella virus can directly infect and replicate in the placenta. Though fetal infection can occur at any stage of pregnancy, outcome is dependent on the timing of maternal infection with respect to gestational age of the fetus. During first trimester, infection rates are highest (81% overall, but 100% infection rate is observed in first 10 weeks), decline to 25% at the end of the second trimester, and again increase to 100% during the last month of gestation. However, infection of a fetus does not result in malformation always. The risk of malformation is inversely proportional to the gestational age. Malformation occurs in 90% of infections during first 2–10 weeks, 34% of infections during 11–18 weeks, and 0–10% for those infected after 18 weeks.

**Pathogenesis**

The mechanisms of fetal damage by rubella virus are poorly understood, though it is known that the structural damage occurs secondary to defective organogenesis. It has been postulated that during maternal viremia, rubella virus reaches the fetus via the chorion. Virus-infected desquamated epithelial and endothelial cells are transported to the fetal circulation and reaching almost every fetal organ, inducing retardation in cell division, cellular apoptosis, interference with the cell cycle and tissue necrosis. Rubella virus is noncytolytic, allows cell survival at the cost of persistent infection, decreased growth rate and shortened survival time. Virus particles may also be retained in secluded tissues like lens, and virus antigens may persist in various target organs with recurrent phases of increased virus production and replication. Noninflammatory response is seen, which is the hallmark of rubella embryopathy. Rubella virus can be isolated postnatally from urine, stool, nasopharyngeal secretions and CSF with CRS. In severely affected infants, virus may persist for up to 1 year of age.

**Clinical Manifestations**

**Box 3** lists the clinical manifestations seen in congenital rubella. The classic triad of CRS consists of sensorineural hearing loss (SNHL), cataracts and heart defects. Half (~50%) of infants with CRS may appear normal at birth, but CNS abnormalities develop with time. Among the clinical manifestations, SNHL is the most common (~58%) abnormality seen in CRS. Deafness may be the only abnormality if infection occurs after 12 weeks' gestation. The retinopathy is usually benign and nonprogressive. World Health Organization (WHO) has provided the following case definitions of CRS:

- **Suspected case:** Any infant younger than 1 year in whom a health worker suspects CRS for presenting with heart disease and/or suspicion of deafness and/or one or more of the following eye signs: cataract, diminished vision, nystagmus, squint, microphthalmus, or congenital glaucoma; or when an infant's mother has a history of suspected or confirmed rubella infection during pregnancy, even when the infant shows no signs of CRS.
- **Clinically confirmed CRS case:** An infant in whom a qualified physician detects two of the complications listed below in section A or one from section A and one from section B:
  - A. Cataracts, congenital glaucoma, congenital heart disease, hearing impairment, pigmentary retinopathy
  - B. Purpura, splenomegaly, microcephaly, mental retardation, meningoencephalitis, radiolucent bone disease, jaundice with onset within 24 hours after birth.
- **Laboratory-confirmed CRS case:** An infant with rubella IgM antibody who has clinically confirmed CRS.
- **Congenital rubella infection:** An infant with rubella IgM antibody who does not have clinically confirmed CRS.

**BOX 3 Clinical manifestations of congenital rubella syndrome**

- **General:** Intrauterine growth retardation, prematurity, stillbirth, abortion
- **Cardiovascular:** Patent ductus arteriosus, pulmonary artery stenosis, coarctation of the aorta, myocarditis, ventricular septal defect, atrial septal defect
- **Ocular (unilateral or bilateral):** Cataract, salt-and-pepper pigmentary retinopathy, cloudy cornea, glaucoma, microphthalmia, subretinal neovascularization
- **Aural:** Hearing loss (usually bilateral, mostly sensorineural)
- **Central nervous system:** Meningoencephalitis, microcephaly, mental retardation, behavioral disorders, autism, intracranial calcifications, chronic progressive panencephalitis, hypotonia, speech defects, encephalographic abnormalities
- **Skin:** Blueberry muffin rash indicating dermal erythropoiesis, chronic rubelliform rash, dermatoglyphic abnormalities
- **Pulmonary:** Interstitial pneumonia
- **Gastrointestinal:** Hepatosplenomegaly, jaundice, hepatitis, splenic fibrosis
- **Hematological:** Thrombocytopenia (usually transient and does not respond to steroid therapy), hemolytic anemia, altered blood group expression
- **Immunological:** Hypogammaglobulinemia, lymphadenopathy, thymic hypoplasia
- **Skeletal:** Radiolucencies of long bones (most commonly seen in metaphyses of distal femur and proximal tibia), large anterior fontanel, micrognathia
- **Endocrine:** Growth hormone deficiency, thyroid disease (hypothyroidism, hyperthyroidism, and thyroiditis), diabetes mellitus (becomes apparent later in second or third decade of life)
- **Genitourinary:** Cryptorchidism, polycystic kidney, inguinal hernia, hypospadias, nephrosclerosis, nephrocalcinosis
- Dental defects

**Diagnosis**

Diagnosis can be confirmed in serum by detecting rubella-specific IgM before 3 months of age, or by detection of rubella IgG between 6 months and 12 months of age. Isolation of rubella virus from pharyngeal secretions, urine, stool, eye discharge, blood and CSF up to 1 year of age confirms the diagnosis.

**Treatment**

No specific treatment is available, only supportive management can be provided. Since neonates with CRS are likely to excrete high concentrations of rubella virus, they should be nursed in isolation to avoid the spread of infection. A multidisciplinary team is required to manage the child. The outcome depends on the severity of organ damage. Heart defects and cataract can be corrected surgically, but damage to CNS is permanent. Long-term follow-up is important, as some abnormalities may develop even beyond the first decade of life.

Effective vaccination program is already available and should be strongly encouraged to eliminate rubella and CRS.

**TOXOPLASMOSIS**

*Toxoplasma gondii* (*T. gondii*) is an obligate intracellular protozoan parasite. Three different strains, type I, II and III with variable virulence have been identified, of which type I and II are found to be associated with congenital toxoplasmosis in humans. Oocyst, excreted in cat feces, is the source of infection to humans. Oocyst may remain viable and infective in warm, moist soil, and raw meat, for up to 1 year and contaminate drinking water. Worldwide, prevalence of congenital toxoplasmosis is 1–10 per 10,000 livebirths, with an overall transmission rate of 33%. High burden of the disease is seen in South America and in some Middle-eastern and low-income countries.

**Transmission**

Vertical transmission can occur in utero or during vaginal delivery. Only primary infection during pregnancy results in congenital toxoplasmosis with an incidence of 40%. However, in women with coexisting AIDS, latent toxoplasmosis may get reactivated resulting in congenital transmission.

Majority of pregnant women with acute infection do not have any obvious symptoms. The risk of infection to the fetus and its severity depends on the gestational age at the time of maternal infection. Fetal transmission rate is 25% in first trimester, 75% in third trimester, and increases to 90% during last few weeks of pregnancy. The severity of the fetal organ damage is inversely proportional to gestational age, earlier infections being the most severe ones. HIV-positive infants with congenital toxoplasmosis have a rapid and progressive course of the disease.

**Pathogenesis**

*Toxoplasma gondii* is highly mobile and travels actively through blood and lymph and across biological barriers including placenta. Congenital toxoplasmosis is caused by the transplacental passage of tachyzoites from mother to fetus. Clinical symptoms and course of infection depend on the bulk of inoculation, virulence of the organism, gestational age at the time of infection, gender, genetic factors and immune status of the mother.

**Clinical Manifestations**

Clinical features of congenital toxoplasmosis vary widely and can manifest at different times before and after birth. Most infected newborns (70–90%) are asymptomatic at birth but up to 80% of them develop learning or visual disabilities later in life. The classic triad consists of chorioretinitis, intracranial calcifications and hydrocephalus and is found in less than 10% of infected infants. The clinical features are summarized in **Box 4**.

**BOX 4 Clinical features of congenital toxoplasmosis**

- Intrauterine growth restriction
- Fever
- Vomiting
- Maculopapular rash
- Anemia
- Generalized lymphadenopathy
- Jaundice
- Hepatosplenomegaly
- Eosinophilia
- Thrombocytopenia
- Abnormal bleeding
- **Ocular manifestations:** Chorioretinitis, chorioretinal scars, strabismus, nystagmus, optic atrophy, microcornea, microphthalmos, cataract, retinal detachment, vitritis, phthisis
- **CNS manifestations:** Meningoencephalitis, intracranial calcifications (mostly diffuse), abnormal cerebrospinal fluid (xanthochromia and pleocytosis), hydrocephalus, microcephaly, seizure disorder, bulging fontanel, abnormal muscle tone, deafness, delayed developmental milestones

**Diagnosis**

A positive toxoplasma IgG in an infant of 12 months of age is considered diagnostic of congenital toxoplasmosis, and is considered the *gold standard* for ultimate and definite laboratory diagnosis. Serological diagnosis can also be made in newborns with positive toxoplasma IgM or IgA antibody titers, 5 or 10 days after birth, respectively (in order to exclude maternal blood contamination). The immunosorbent agglutination assay (ISAGA) method for IgM and the enzyme-linked immunosorbent assay (ELISA) method for IgA have been found to have superior performance for the diagnosis of congenital toxoplasmosis in the

infant. However, it appears that the IgM ISAGA is a more sensitive method than the IgM ELISA for the diagnosis of congenital disease.

Analysis of CSF can be helpful in infants suspected of being infected with *T. gondii* and who have clinical signs and imaging studies suggestive of CNS involvement. A positive *T. gondii*-specific IgM in fluid CSF is diagnostic of congenital disease, whereas positive toxoplasma IgG titers probably reflect passive transfer of serum toxoplasma IgG. A positive *T. gondii* PCR in the CSF, peripheral blood and urine of the newborn is considered diagnostic of congenital toxoplasmosis. Congenital toxoplasmosis is one of the rare entities that can produce CSF eosinophilia or extremely high levels of protein (up to 1,000 g/dL).

## Treatment

Currently, WHO and the Centers for Disease Control and Prevention (CDC) have recommended a combination therapy with pyrimethamine, sulfadiazine and leucovorin as the standard treatment for neonates with congenital toxoplasmosis. Sulfadiazine is used at a dose of 100 mg/kg/day in two divided doses for up to 1 year; pyrimethamine is used at a dose of 1 mg/kg/day for first 6 months, then 1 mg/kg/day three times per week in second 6 months. Both these drugs are used along with folinic acid (leucovorin) at a dose of 5–10 mg three times per week. In resistant cases, trimethoprim-sulfamethoxazole, clindamycin and azithromycin may be tried in consultation with infectious disease specialist. Duration of therapy is based on severity of symptoms, age of the patient at the time of diagnosis and response to therapy. Prolonged therapy, often up to 1 year, is recommended.

## HERPES SIMPLEX VIRUS

Herpes simplex virus (HSV) 1 and 2 are uncommon, but important causes of neonatal morbidity, occurring in 1 of 3,200 livebirths, though the prevalence of genital HSV infection varies from country to country and among different ethnic backgrounds. HSV 2 is mainly associated with genital infection and commonly results in neonatal infection. However, cases occurring after HSV-1 have also been reported. In most cases of neonatal infection, mothers do not have an active genital lesion at the time of delivery.

## Transmission

Majority of the neonatal infections are acquired intrapartum (about 85%). Infants born to mothers with primary genital herpes infections at the time of delivery have 50% risk of developing infection compared with 25% risk when mothers already are seropositive against HSV-1 (nonprimary first episode) and less than 2% risk when mothers are seropositive against HSV-2 and having recurrence of infection.

## Clinical Manifestations

The classical triad of neonatal HSV infection consists of cutaneous manifestations, ophthalmologic findings and neurologic involvement. The clinical features are listed in **Box 5**. Neonatal HSV typically presents within first 1–3 weeks after birth but presentation may be delayed up to 4–6 weeks of age. Neonates with disseminated and skin, eyes, and/or mouth (SEM) HSV disease present earlier, at 10–12 days of age, whereas infants with CNS disease present later, at 17–19 days of age. Approximately, 50% of infants with neonatal HSV disease have CNS involvement, and approximately 70% have characteristic vesicular skin lesions. At least 50% of patients suffer from long-term sequelae. Hemorrhagic pneumonitis, severe coagulopathy, liver failure, seizures and meningoencephalitis are associated with poor prognosis.

## BOX 5 Clinical features of congenital herpes simplex infection

### In utero infection

- *Skin*: Scarring, active vesicular lesions, hypo/hyperpigmentation, aplasia cutis, erythematous macular exanthem
- *Eyes*: Microphthalmia, retinal dysplasia, optic atrophy, chorioretinitis
- *Central nervous system*: Microcephaly, encephalomalacia, hydranencephaly, intracranial calcification

### Intrapartum or postpartum infection

- *Disseminated disease*: It involves multiple organs, including lung, liver, adrenals, skin, eye and brain. Common manifestations include poor feeding, lethargy, fever, apnea, convulsion, respiratory distress, hepatomegaly, jaundice and disseminated intravascular coagulation
- *CNS disease with or without skin lesions*: Common manifestations include seizures, lethargy/irritability, tremors, temperature instability, bulging fontanel
- *Disease limited to the skin, eyes and/or mouth disease*: Common manifestations include vesicles or zoster-like eruptions on skin, eyes and mouth.

## Diagnosis

Since most of the affected newborns are born to mothers who do not have current active genital HSV lesions, a high level of suspicion is necessary to diagnose HSV infection in acutely sick infants. Viral cultures should be collected from various sites, including mouth, nasopharynx, conjunctivae, rectum, skin vesicles, urine, stool, blood and CSF after 48 hours of age. For diagnosing HSV encephalitis, HSV-PCR testing should be done from CSF, though it should be remembered that one negative HSV-PCR test result does not completely rule out HSV infection and these neonates must be monitored closely up to 4–6 weeks of age. Electroencephalography and brain imaging are useful in infants where CNS infection is suspected clinically despite negative HSV-PCR results.

## Treatment

In the presence of active genital HSV lesions or prodromal symptoms at the time of delivery, cesarean section should be performed to reduce the risk of neonatal HSV transmission. Breastfeeding is not a contraindication unless there are active lesions over the breasts. Mother should wash hands before touching the baby.

All infants with suspected or diagnosed HSV infection must be treated with intravenous acyclovir at a dose of 60 mg/kg/day in 3 divided doses. The treatment should be started promptly, especially in case of disseminated infections as the starting time is crucial for prognosis. HSV infections localized to skin, eyes and mucous membranes need treatment for 14 days, whereas CNS or disseminated infections require therapy for 21 days.

## CONGENITAL VARICELLA

The incidence of varicella during pregnancy is 1–5 cases per 10,000 pregnancies. Transplacental transfer of varicella-zoster virus causes spontaneous abortion, fetal demise, and congenital anomalies. Fetal infection in first 20 weeks of gestation can result in a constellation of anomalies known as congenital varicella syndrome (CVS). The incidence of CVS is approximately 1–2%, risk increases if the infection occurs during 13–20 weeks. About 30% of symptomatic infants die in the first postnatal months. Varicella can also be life-threatening in neonates who acquire infection during delivery. Perinatal acquisition of the disease occurs in the newborn within first 10 days after birth if the mother is infected from 5 days before to 2 days after delivery. Clinical manifestations and management issues of both congenital varicella and perinatal varicella are discussed in Section 31 (Chapter 31.6).

## CONGENITAL SYPHILIS

Syphilis is a systemic sexually transmitted disease caused by the spirochete, *Treponema pallidum*. In spite of availability of accurate diagnostic tests and effective treatment, about 11 million people acquire new infections annually even today. Nearly 1.5 million pregnant women are infected with syphilis each year, and approximately half of them remain untreated and face adverse fetal outcome. As per WHO estimation, in 2009, congenital syphilis led to 2.6 million stillbirths and an additional 3.1 million neonatal deaths. In developing countries, mother-to-child transmission of syphilis contributes to one-fourth of all stillbirths and 11% of neonatal deaths. In India, seroprevalence among pregnant women is approximately 1%.

### Transmission

Intrauterine transmission of infection usually takes place between the 16th and 28th weeks of gestation, though it may occur as early as 9 weeks. The risk of transmission is directly proportional to the stage of maternal syphilis during pregnancy and gestational age of the fetus when maternal infection is acquired. In early maternal syphilis, the risk of fetal transmission can be as high as 80%, whereas infectivity decreases in late syphilis. Highest level of spirochetemia is observed during the first 2 years after infection and decreases slowly thereafter because of the development of acquired immunity. After an infection with syphilis, it takes 10–45 days for blood tests to become positive; therefore, an initial negative test does not rule out infection. High-risk pregnant women negative in the first test should be tested again later in the pregnancy or at the time of delivery.

### Clinical Manifestations

Congenital syphilis is divided classically into early and late disease. Early congenital syphilis manifests during the first 2 postnatal years (**Box 6**) and late after 2 years. Approximately, 30–40% of fetuses with congenital syphilis are stillborn, and approximately 75% of liveborn infants remain asymptomatic at birth. Most of the affected children develop varied symptoms between 3 weeks and 14 weeks after birth. Late congenital syphilis is characterized by Hutchinson's triad—interstitial keratitis, Hutchinson's teeth and SNHL.

### Diagnosis

Confirmation of the diagnosis requires demonstration of *T. pallidum* in fetal or neonatal tissues or in the placenta in dark field microscopy. Desquamated or ulcerative skin lesions or snuffles should be examined for spirochetes by dark field microscopy or fluorescent antibody techniques. Treponemal and nontreponemal serological tests can be done to diagnose infected neonates. Treponemal tests include fluorescent treponemal antibody absorption (FTA-ABS) and the particle agglutination (TP-PA) tests. Nontreponemal tests are the Venereal Disease Research Laboratory (VDRL) slide test and the rapid plasma reagin (RPR) test. Any positive nontreponemal test in the infant must be confirmed with a treponemal test. If the neonatal antibody titers are more than four times that of the mother, it indicates fetal infection. Moreover, transplacentally acquired nontreponemal (VDRL or RPR) antibody disappears in uninfected infants by 6 months of age. Passively acquired treponemal antibody [FTA-ABS and/or microhemagglutination assay (MHA-TP)] disappears by 15–18 months.

### Treatment

Infants with presumptive or confirmed congenital syphilis should be treated with aqueous penicillin G, 50,000 U/kg intravenously

#### BOX 6 Clinical manifestations of early congenital syphilis

- **Reticuloendothelial:** Generalized, nontender lymphadenopathy, anemia (hemolytic or nonhemolytic), leukopenia or leukocytosis, thrombocytopenia, hepatosplenomegaly, extramedullary hematopoiesis.
- **Mucocutaneous:** Snuffles, i.e., thick or bloody nasal discharge, laryngitis, coppery-brown maculopapular rash involving palms and soles followed by desquamation, blistering and crusting, mucous patches on palate and perineum, perioral and perianal condyloma lata. Skin lesions are highly infectious
- **Skeletal:** Symmetrical long bone lesions, more commonly seen in lower extremities, metaphyseal osteochondritis with mild to severe destructive lesions, developing within 5 weeks of infection, Wimberger sign, i.e., demineralization and destruction of the proximal tibial metaphyses, diaphyseal periostitis with periosteal new bone formation, developing after 16 weeks of infection, osteitis producing alternate linear bands of translucency and radiodensity in long bones giving a *celery stick* appearance and dactylitis with involvement of metacarpals, metatarsals and proximal phalanges.
- **Neurological:** Features of acute meningitis with cerebrospinal fluid shows pleocytosis, elevated protein low glucose and reactive Venereal Disease Research Laboratory test, untreated chronic meningovascular syphilis may lead to hydrocephalus, cerebral infarctions and cranial nerve palsies
- **Ocular:** Salt and pepper chorioretinitis, glaucoma, uveitis
- **Renal:** Immune complex mediated nephrotic syndrome seen after 2–3 months of infection
- **Pulmonary:** Pneumonia alba or obliterative fibrosis
- **Heart:** Myocarditis
- **Gastrointestinal system:** Pancreatitis, gastrointestinal inflammation and fibrosis

every 12 hours (1 week of age or younger) and every 8 hours (older than 1 week) for a total of 10 days as outlined by American Academy of Pediatrics.

### Follow-up

Infants with congenital syphilis should have serial nontreponemal tests done at 1, 2, 4, 6 and 12 months. When children are treated appropriately, the nontreponemal titer becomes nonreactive by 12 months of age. A second course of treatment should be considered in children with persistently positive titers, even at a low level. After treatment, infants with initial abnormal CSF (increased cell count or protein and positive VDRL in CSF) should have a repeat CSF examination done at 6 months of age. A positive CSF VDRL 6 months after initial treatment necessitates for a second course.

## HEPATITIS VIRUS

Acute viral hepatitis is the most common cause of jaundice in pregnancy, although the course of most of the viral infections is not affected by pregnancy itself. The incidence of vertical transmission of hepatitis A virus (HAV) infection during pregnancy or postpartum period is rare.

Hepatitis B virus (HBV) does not cross the placenta because of its large size, and cannot infect the fetus unless the maternal-fetal barrier is broken by some procedure, such as amniocentesis. Infected women transmit HBV infection to the infant during delivery. Without adequate active and passive prophylaxis, the newborn remains at high risk (70–90%) to develop a chronic HBV infection, and its long-term complications. Breastfeeding by a surface antigen of the HBV (HBsAg) positive mother does not increase the risk for acquisition of HBV infection in the infant. Perinatal acquired hepatitis B infection in a neonate born to HBsAg positive mother can be prevented by hepatitis B

vaccine and hepatitis B immunoglobulin (0.5 mL intramuscular) administered 12–24 hours within birth. This has shown to be 85–95% effective.

The prevalence of HCV among pregnant women is approximately 1%, and the rate of vertical transmission is 4–7% per pregnancy in women with detectable viremia. Mother-to-infant transmission of HCV infection can occur in utero, intrapartum or during perinatal period. The average rate of infection is approximately 4/100 infants. In utero transmission rate is about 33–50%. Transmission rate increases with HCV-RNA positivity at the time of delivery, high viral load more than  $10^6$  IU/mL, rupture of membrane more than 6 hours before delivery and fetal scalp electrode monitoring, female gender and coinfection with HIV. Infants infected through vertical transmission are otherwise asymptomatic, except elevated transaminase levels. However, cirrhosis, and rarely, hepatocellular carcinoma have been reported during childhood.

Perinatal transmission with hepatitis D virus is rare. Hepatitis E and G virus infection does not have any known effects on the fetus. However, premature delivery with high infant mortality of up to 33% has been observed.

## CONGENITAL TUBERCULOSIS

Tuberculosis remains a major global health problem and one of the leading infectious causes of death. The incidence of tuberculosis in women of child-bearing age is 2% in countries where the disease is endemic. Congenital tuberculosis is relatively rare because genital tuberculosis and tuberculous endometritis are associated with infertility. Till date, approximately 340 cases have been reported in literature.

### Transmission

Congenital tuberculosis is caused by *Mycobacterium tuberculosis* and the disease occurs when maternal tuberculosis involves the genital tract or the placenta. Congenital tuberculosis is acquired through various routes and, therefore, the clinical manifestations in the newborn can vary.

#### Transplacental

Transmission occurs by hematogenous spread of the maternal disease at any time of pregnancy. Miliary lesions are seen in placenta and the predominant organ involved in fetus is the liver.

#### Perinatal

Inhalation or aspiration of infected materials from maternal genitourinary tuberculosis during passage through the birth canal results in pulmonary or gastrointestinal tuberculosis in the neonate. The disease manifests approximately 3 weeks after birth.

#### Postnatal

Transmission from open maternal pulmonary tuberculosis or other close contacts can result in pulmonary tuberculosis in neonates.

### Clinical Manifestations

Signs of congenital tuberculosis are usually evident during the second or third week after birth and simulate neonatal sepsis of other bacterial/viral origin or any other intrauterine infections, such as syphilis or CMV infection. Common clinical manifestations include low birthweight, hepatosplenomegaly, respiratory distress,

fever, lymphadenopathy, poor feeding, lethargy or irritability, abdominal distension, ear discharge and papular skin lesions. Uncommon findings include vomiting, seizures, apnea, cyanosis, jaundice, meningitis, petechiae, progressively deteriorating liver function or sudden death.

### Diagnosis

Diagnosis is difficult because more than 50% of mothers remain asymptomatic and often are diagnosed only after congenital tuberculosis is diagnosed in their neonates. Congenital tuberculosis should be suspected in newborns who have nonresolving pneumonia, not responding to antibiotic therapy, persistent fever and hepatosplenomegaly, high CSF lymphocyte count in absence of any bacterial pathogen isolated on culture. Neonates born to mothers with known tuberculosis, especially in human immunodeficiency virus positive cases, should be thoroughly investigated to rule out congenital tuberculosis.

Diagnostic work-up includes chest X-ray, gastric aspirate examination for acid-fast bacilli (AFB), lumbar puncture and culture of body fluids. Chest X-ray may show scattered infiltrates, bronchopneumonia or consolidation. Tuberculin skin tests are usually negative in newborns with congenital or perinatally acquired infection. Hepatic granulomas may be seen in liver biopsy. Fluorescent staining of early morning gastric aspirate is relatively more sensitive, but the overall yield is less than 50%. AFB cultures have their own limitations. A minimum of 1–6 weeks is required for *Mycobacterium tuberculosis* to grow even in liquid media and the organism is isolated in less than 75% cases with other clinical evidence of pulmonary tuberculosis. PCR and other nucleic acid amplification tests can be done. Histopathological examination of placenta for granulomatous lesions and demonstration of AFB should be done in addition to routine work-up for tuberculosis in the mother.

### Treatment

Treatment should be started with a combination of isoniazid, rifampin, pyrazinamide and an aminoglycoside, such as amikacin. Total duration of therapy depends on the clinical course of the disease. Most of the studies recommend 1 year therapy (4-drug treatment for 2–3 months followed by isoniazid, rifampin for 9–10 months). All the antitubercular drugs are rapidly absorbed and well tolerated in neonates. To avoid neurotoxicity, pyridoxine (vitamin B<sub>6</sub>) should be added in exclusively breastfed infants. Corticosteroids are indicated in neonates with meningitis and pericardial or pleural involvement. In the absence of prompt treatment, prognosis may be poor, almost 50% of the neonates with congenital tuberculosis may die.

Asymptomatic infants born to mothers with active tuberculosis should receive isoniazid prophylaxis in most cases for 3 months, after which time a tuberculin skin test should be done to determine infection and need for further evaluation and treatment.

## LESS COMMON ORGANISMS

Effect of congenital infections caused by less common organisms, such as parvovirus, listeria, coxsackievirus, echovirus, measles, mumps, poliovirus, lymphocytic choriomeningitis virus (LCMV), West Nile virus and influenza virus is discussed in **Table 1**. The overall risk of symptomatic infection by these organisms is relatively low and often overlooked.

### IN A NUTSHELL

1. The acronym *CHEAP TORCHES* captures the expanded list of organisms that cause congenital infections in the newborn.
2. Cytomegalovirus, rubella and toxoplasmosis are the most common causes of chronic intrauterine infection in the fetus and newborn.
3. Herpes simplex infection is characterized by the triad of cutaneous, ophthalmic and neurologic involvement.
4. Congenital tuberculosis should be suspected in newborns who have nonresolving pneumonia, persistent fever and hepatosplenomegaly, in the absence of any bacterial pathogen isolated on culture.

**Table 1** Clinical manifestations of less common congenital infections

Infective agent	Effects on fetus
<i>Plasmodium</i> spp	<p>Malaria infection during pregnancy may lead to abortion, low birthweight and intrauterine growth restriction, premature delivery, congenital infection or perinatal death</p> <p>Congenital malaria is defined as the presence of malarial parasites (ring forms) in the peripheral smear of the newborn within first 7 days of life</p> <p>Malarial infection may be acquired by the fetus in utero or during delivery</p> <p>Clinical manifestations in newborns are indistinguishable from neonatal sepsis and include fever, irritability, refusal to feed, anemia, jaundice and hepatosplenomegaly</p> <p>Diagnosis is made by examination of peripheral blood smears, although these can be negative in low parasitemia (&lt;50 parasites/<math>\mu</math>L blood). Malaria can also be detected by polymerase chain reaction from cord blood</p>
Parvovirus B19	Abortion, fetal anemia, hydrops fetalis, myocarditis, intrauterine fetal demise
<i>Listeria monocytogenes</i>	<p>Infection in early pregnancy may lead to abortion. Later infection may cause stillbirth or preterm labor associated with meconium-stained or greenish amniotic fluid and neonatal infection. Presents with first 2–3 days after birth with features of neonatal sepsis, congenital pneumonia or disseminated granulomatous lesions called granulomatosis infantisepticum. Microabscesses and granulomas containing the organism can be demonstrated in different organs, particularly the lungs, liver and spleen</p> <p>Ampicillin plus an aminoglycoside is the treatment of choice in infected neonates</p>
Coxsackie virus	<p>Complications are more common with group B infection than group A</p> <p>Intrauterine exposure to coxsackie B virus (CBV) may be associated with development of insulin-dependent diabetes mellitus (IDDM) in later life</p> <p>Infection early in pregnancy can cause miscarriage, congenital cardiac anomalies, birth defects and orofacial clefts</p> <p>Transplacental passage of CBV toward the end of gestation may produce severe maculopapular rash, pneumonia, myocarditis and meningoencephalitis, which may be fatal</p>
Echovirus	Congenital anomalies, hepatitis, peritonitis, coagulopathy, fetal death and IDDM in offspring in later life have been reported
Measles virus	Measles during pregnancy increases the rate of maternal complications and mortality. Fetal infection increases the chances of abortions, early fetal death and premature delivery
Mumps virus	<p>Increased risk of spontaneous abortions and fetal death</p> <p>A possible association between maternal mumps during pregnancy and fetal cardiomyopathy, especially endocardial fibroelastosis has been reported</p> <p>Perinatal mumps infection following vertical transmission is rare, may lead to respiratory distress and pulmonary hypertension. Prognosis is good</p>
Poliovirus	<p>Perinatal transmission is seen when maternal infection occurs later in pregnancy. Associated with increased rate of spontaneous abortions and stillbirths and with paralysis of the newborn infants (congenital polio)</p> <p>A possible association of intrauterine polio infection with schizophrenia has been documented</p>
Lymphocytic choriomeningitis virus	Chorioretinitis, hydrocephalus, mental retardation, visual impairment, intrauterine fetal death
West Nile virus	Infants born to mothers with symptomatic West Nile virus infection within 3 weeks prior to delivery may develop symptomatic disease shortly after birth
Influenza virus	Risk of fetal infection and congenital abnormalities is unclear

# Section 16 NEUROLOGICAL PROBLEMS OF THE NEWBORN INFANT

**Section Editor** Siddarth Ramji

## Chapter 16.1

### Seizures in the Neonates

Amit Upadhyay, Pranjali Saxena

Neonatal seizures are the frequent and distinctive clinical manifestation of neurological dysfunction in the newborn infant. These are to be actually recognized and managed for broadly three reasons. Firstly, they are significant cause of neonatal morbidity and mortality. Secondly, they may interfere with treatment measures, such as nutrition and ventilation for associated disorders. Thirdly, the seizures have been shown to be detrimental to developing brain and may cause cognitive/neurological impairment and epileptic disorders in later life.

#### DEFINITION

A seizure is defined clinically as a paroxysmal alteration in neurologic function, i.e., motor, behavior and/or autonomic function. The seizures can be:

- **Epileptic seizures** Clinical phenomena associated with corresponding electroencephalography (EEG) seizure activity, e.g., clonic seizures.
- **Nonepileptic seizures** Clinical seizures without corresponding EEG correlate, e.g., subtle and generalized tonic seizures.
- **EEG seizures** Abnormal EEG activity with no clinical correlation.

#### INCIDENCE

The National Neonatal Perinatal Database (NNPD 2002–03) data from 18 tertiary care units across India, has reported its incidence of 10.3 per 1,000 livebirths. The incidence was found to increase with decreasing gestation and birthweight—with preterm infants reporting almost twice the incidence as compared to term neonates (20.8 and 8.4 per 1,000 live-births respectively). In developed countries, the incidence in babies under 1,500 g has been reported to be as high as 57.5 per 1,000 in very low birthweight (VLBW) infants as compared to only 2.8 per 1,000 for infants with birthweights of 2,500–3,999 g in population based studies.

#### ETIOLOGY

The common causes of seizures as per NNPD from India are hypoxic ischemic encephalopathy, metabolic disturbances (hypoglycemia and hypocalcemia), and meningitis. Common causes of neonatal seizures are discussed below.

#### Birth Asphyxia

It is the most common cause of neonatal seizures in both full-term and premature infants. Multiple factors like hypoglycemia, hypocalcemia, polycythemia, intracranial bleed, etc., may contribute in isolation or in combination, to seizures in babies

with perinatal asphyxia. Seizures usually occur within the first 24 hours of birth. Seizures occurring within 4–6 hours of birth suggest intrauterine insult. Subtle, multifocal, clonic or tonic seizures can occur. It will be associated with low Apgar scores, delayed cry (for >3 min), low pH and high base deficit in arterial blood gas (ABG) analysis.

#### Intracranial Hemorrhage

Seizures due to subarachnoid, intraparenchymal or subdural hemorrhage occur mainly in term neonates, while seizures secondary to intraventricular hemorrhage (IVH) occur in preterm infants. Most seizures due to intracranial hemorrhage (ICH) occur between 2 days to 7 days of age. Subarachnoid hemorrhage often present as seizures in a *well-baby* on 2nd–3rd day of life.

#### Intracranial Infection

Seizures due to bacterial infections like meningitis occur only in or after latter half of the first week. Seizures associated with herpes simplex encephalitis also tend to occur in late neonatal period. Nonbacterial infections like neonatal encephalitis due to toxoplasma, rubella, and cytomegalovirus infection can cause seizure episodes with in the first 3 days of life.

#### Developmental Defects

Aberrations of brain development can result in seizures, which begin at any time during the neonatal period. Most aberrations are of cerebral cortical dysgenesis and neuronal migration disorders (lissencephaly, pachygyria, and polymicrogyria). They can be best diagnosed by magnetic resonance imaging (MRI) of brain.

#### Metabolic Disturbances

Hypoglycemia is most frequent in high-risk babies like preterm, small or large for gestation. The onset is usually in first 2 days. It is diagnosed by screening with glucostix and confirmed by standard laboratory values. Early onset hypocalcemia occurs in first 3 days of life most often in preterm, infants of diabetic mothers and babies with perinatal asphyxia. Late onset hypoglycemia occurs in full-term infants who avidly consume cow milk with a suboptimal ratio of calcium or magnesium to phosphorus. Hypomagnesemia is a frequent accompaniment.

#### Other Metabolic Disturbances

These are uncommon causes of seizures and include hyponatremia, hypernatremia, hyperammonemia, amino acid and organic acid abnormalities, mitochondrial disturbances, peroxisomal disorders, pyridoxine dependency, folinic acid responsive seizures, glucose transporter deficiency among other rare ones.

#### Local Anesthetic Intoxication

It occurs as a result of neonatal intoxication with local anesthetics. They can be inadvertently injected into the infant's scalp, during placement of paracervical, pudendal, or epidural block or local anesthesia for episiotomy. Two distinguishing features of local

anesthetic intoxication are: (1) pupils fixed to light and often dilated; and (2) eye movements fixed to the oculocephalic (doll's eyes) reflex. These infants improve over the first 24–48 hours (if properly supported) and anticonvulsant drugs are of questionable value.

### Drug Withdrawal

A rare cause but not an infrequent cause in developing countries. The drugs particularly involved are narcotic-analgesics (e.g., methadone), sedative-hypnotics (e.g., shorter-acting barbiturates), tricyclic antidepressants, cocaine, alcohol, etc.

### Syndromes

Epileptic syndromes are benign familial neonatal seizures, benign idiopathic neonatal seizures (5th-day fits), early myoclonic encephalopathy, early infantile epileptic encephalopathy (Ohtahara syndrome) and malignant migrating partial seizures. Nonepileptic syndromes are benign neonatal sleep myoclonus and hyperekplexia.

### PATHOPHYSIOLOGY

Seizure activity results from an excessive synchronous electrical discharge (i.e., depolarization) of neurons within the central nervous system. Depolarization is produced by the influx of sodium ( $\text{Na}^+$ ), and repolarization is produced by the efflux of potassium ( $\text{K}^+$ ). A potential across the membrane is maintained by energy dependent Na-K-ATPase pump, which extrudes  $\text{Na}^+$  and takes in  $\text{K}^+$ . Excessive neuronal depolarization may result from following reasons:

- Disturbance in energy production (e.g., hypoxemia-ischemia and hypoglycemia) can result in a failure of the ATP-dependent  $\text{Na}^+$ - $\text{K}^+$  pump.
- Relative excess of excitatory versus inhibitory neurotransmitters can result in an excessive rate of depolarization as in hypoxia-ischemia and hypoglycemia causes increase in extracellular levels of glutamate (the principal excitatory neurotransmitter in cortex) because of excessive synaptic release and diminished reuptake by energy-dependent transport in both presynaptic nerve endings and glia.
- A relative deficiency of inhibitory compared to excitatory neurotransmitters also results in an excessive rate of depolarization. The brain concentration of gamma-aminobutyric acid (GABA), the major inhibitory neurotransmitter, is decreased when the activity of its synthetic enzyme, glutamic acid decarboxylase, is depressed. Calcium and magnesium normally inhibits  $\text{Na}^+$  influx by interacting with the neuronal membrane; thus, hypocalcemia or hypomagnesemia would be expected to cause an increase in  $\text{Na}^+$  influx and depolarization.

### EVOLVING CONCEPTS IN SEIZURE GENERATION

Seizures in newborns differ from those observed in older infants and children as they rarely have organized generalized tonic-clonic activity. Even seizure activity in premature infants differs from those in full-term infants. The reasons for these variation relate to developmental differences in neuroanatomy and neurophysiology.

### Neuroanatomical Features

Neuroanatomical developmental processes that occur in the perinatal period are an organization of events. These events include the attainment of proper orientation, alignment, layering (i.e., lamination) of cortical neurons, elaboration of axonal and dendritic ramifications, and establishment of synaptic connections. Only lamination is well developed in the human newborn while neuritic

outgrowth and synaptogenesis are less developed. So, the cortical connectivity to propagate and sustain a generalized seizure cannot occur in developing neonatal human brain.

### Neurophysiological Features

Factors implicated in seizures in human newborn are as follows:

- In limbic and neocortical regions, development of excitatory mechanisms such as N-methyl-D-aspartate (NMDA) and  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors are over expressed, and exhibit multiple properties that enhance excitation.
- GABA receptors have excitatory rather than inhibitory activity in perinatal neurons because of elevated intraneuronal  $\text{Cl}^-$  concentration. This is a result of increased expression of NKCC1 receptors (sodium-potassium-chloride cotransporter) which mediates chloride influx, with relatively decreased expression of KCC2 receptors (potassium-chloride-cotransporter), which mediates  $\text{Cl}^-$  efflux (**Figs 1A and B**).
- Deficient development of substantia nigra system which mediates inhibition of seizures.
- *Impaired propagation of electrical seizures from core of brain to surface*: Studies on rat models demonstrated that certain epileptic phenomena can occur without any surface-recorded EEG discharges, and such phenomena can be generated at subcortical (i.e., deep limbic, diencephalic, brain stem) regions. Likewise, neurons of the inferior colliculus of human midbrain are particularly sensitive to injury by hypoxic-ischemic insults, manifesting as subtle seizures. Thus they may not exhibit simultaneous electrographic discharge and account for the inconsistent electroclinical correlation in subtle seizures in newborns.

### Physiological Changes during Seizures

During seizure the metabolic demand of brain increases. The blood glucose may remain normal or increases but brain glucose falls markedly with a rise in lactate levels. Systemic blood pressure rises to increase the cerebral blood flow, so as to meet the metabolic demand of brain. These short-term changes are followed by the changes in cell structure and synaptic linkages leading to long-term neurological abnormalities. Thus, recurrent seizures are detrimental to developing neonatal brain.

### CLASSIFICATION

Four essential clinical seizure types have been recognized: subtle, clonic, tonic, and myoclonic. Clinical seizure associated with electrical activity is true form of seizures. However, electroclinical dissociation (ECD) is not uncommon. ECD can be

**Figures 1A and B:** (A)  $\text{Cl}^-$  influx and hyperpolarization (inhibition); (B)  $\text{Cl}^-$  efflux and depolarization (excitation)

**Abbreviations:** GABA, gamma-aminobutyric acid; NKCC1, sodium-potassium-chloride cotransporter; KCC2, potassium-chloride-cotransporter.

**Table 1** Electrical activity in different types of clinical seizures

Clinical seizure	Electroencephalographic seizure	
	Common	Uncommon
Subtle	+	
Clonic		
• Focal	+	
• Multifocal	++	
Tonic		
• Focal	+	
• Generalized		+
Myoclonic		
• Focal, multifocal		+
• Generalized	+	

either ways. Some clinical seizures may not be associated with electrical correlation and vice versa. Subtle, multifocal clonic and generalized myoclonic seizures are more likely to be associated with electrical activity rather than generalized tonic seizures (Table 1).

### Subtle Seizures

It is called subtle because the clinical manifestations are mild and frequently missed. They are probably the most common type. They constitute about 50% of neonatal seizures. Subtle seizure include ocular-tonic horizontal deviation of eyes or sustained eye opening with ocular fixation or cycled fluttering; oral-facial-lingual movements—chewing, tongue-thrusting, lip-smacking, etc.; limb movements—cycling, paddling, boxing-jabs, etc.; autonomic phenomena—tachycardia or bradycardia, apnea may be a rare manifestation of seizures. Apnea due to seizure activity has an accelerated or a normal heart rate when evaluated 20 seconds after onset. EEG correlation is variable.

### Clonic Seizures

It represents the seizure type associated most consistently with time-synchronized EEG seizure activity. They constitute about 25–30% of neonatal seizures. It has rhythmic and usually rather slow (approximately one to three jerks per second at the onset, with the rate progressively declining with the seizure). Clonic seizures are categorized as *focal* or *multifocal*. EEG correlation is common with focal-clonic type of seizure. Multifocal refers to clinical activity that involves more than one site, asynchronous, migratory and usually crossing midline, whereas generalized refers to clinical activity that is diffusely bilateral, synchronous, and nonmigratory.

### Tonic Seizures

It is sustained flexion or extension of axial or appendicular muscle groups. They constitute about 5% of neonatal seizures. These seizures may be focal or generalized and may resemble decerebrate (tonic extension of all limbs) or decorticate posturing (flexion of upper limbs and extension of lower limbs). They are most common seen in perinatal asphyxia. So incidence is more in studies where asphyxia is predominant cause of seizure. Usually they are not associated with EEG changes.

### Myoclonic Seizures

It is single or multiple lightning fast jerks of the upper or lower limbs and are usually distinguished from clonic movements because of more rapid speed of myoclonic jerks, absence of slow return and predilection for flexor muscle groups. They constitute

about 15–20% of neonatal seizures. Common changes seen on the EEG include focal sharp waves and hypsarrhythmia.

## SEIZURE MIMICS

### Jitteriness or Tremors

These are most common condition mimicking seizures in neonates. These are known as rhythmic segmental myoclonus. They are commonly seen in hypoglycemia, hypocalcemia and in some normal neonates. These are characterized by rhythmic fast movements (4–6/s) which are provoked by stimulus like gently pulling the leg or hand or with elicitation of startle or Moro reflex. These are not associated with gaze abnormality or other autonomic and EEG changes.

### Benign Neonatal Sleep Myoclonus

The nonepileptiform myoclonus is of unclear mechanism but may be related to a transient dysmaturity of the brainstem reticular activating system. It usually presents in the first week of life. It occurs only during sleep, and is rapidly abolished by arousal; it can also be precipitated by gentle rhythmic rocking or tactile stimuli. EEG is normal in this condition. It resolves spontaneously over weeks to months. Long-term outcome is good and epilepsy does not develop later. Early diagnosis is important as use of barbiturates worsen this condition.

## APPROACH TO NEONATAL SEIZURES

### Seizure History

Complete seizure description with history of associated eye movements, restraint of episode by gentle hold or passive flexion of the affected limb, change in color of skin (mottling or cyanosis) and whether the infant was conscious or sleeping at the time of seizure should be elicited. The day of life on which the seizures occurred may provide an important clue to its diagnosis. While seizures occurring on day 0–3 might be related to perinatal asphyxia, ICH, and metabolic causes, those occurring on 4–7 day or beyond may be due to sepsis, meningitis, metabolic causes and developmental defects.

### Others

Obtain information suggesting perinatal asphyxia, intrauterine infections or diabetes in mother. A history of sudden increase in fetal movements may be suggestive of intrauterine convulsions. Information of place of delivery is important as babies born at home may not have received Vitamin K and hemorrhagic disease of newborn can lead to ICH. Features like lethargy, poor activity, drowsiness, and vomiting after initiation of breastfeeding may be suggestive of inborn errors of metabolism. Late onset hypocalcemia consequent to hyperphosphatemia, should be considered in the presence of cow's milk feeding.

### Family History

History of consanguinity in parents, history of seizures or mental retardation in family and early fetal/neonatal deaths could be suggestive of inborn errors of metabolism. History of seizures in either parent or sib(s) in the neonatal period may suggest benign familial neonatal convulsions (BFNC).

### Examination

The neonate should also be examined for the presence of any obvious malformations or dysmorphic features. Presence of hepatosplenomegaly or an abnormal urine odor may be suggestive of inborn error of metabolism (IEM). The skin should be examined

for the presence of any neurocutaneous markers. Presence of sepsis, hypoglycemia, jaundice, hepatomegaly in a baby may point towards galactosemia. Neurological state like lethargy/shrill cry and presence of a bulging anterior fontanel may be suggestive of meningitis or ICH. Sequential neurological examination at 8–12 hourly intervals may be more important and revealing than a single one time examination.

## INVESTIGATIONS

Investigations should be individualized with an emphasis on early identification of correctable cause. It should proceed in parallel with stabilization of vitals. *Essential investigations* which need to be done in all babies include blood sugar, serum electrolytes (Na, Ca, Mg), ABG, cerebrospinal fluid (CSF) examination, cranial ultrasound (US), and EEG. An ABG should be done to look for evidence of hypoxia and IEM. CSF study may be withheld if severe cardiorespiratory compromise is present or even omitted in infants with severe birth asphyxia (documented abnormal cord pH/base excess and onset of seizures within 12–24 hours). *Additional investigations* may be considered in neonates who do not respond to anticonvulsant drugs or earlier in neonates with specific features or in unexplained clinical scenario. These include neuroimaging [computed tomography (CT), MRI], detailed screen for congenital infections (TORCH) and work-up for IEM.

## MANAGEMENT

### Initial Management

The first step in successful management of seizures is to admit and nurse the baby in thermoneutral environment and to ensure warmth, airway, breathing, and circulation (TABC). Oxygen should be started, IV access should be secured, and blood should be collected for glucose and other investigations. A brief relevant history be obtained and quick clinical examination should be performed. All this should be done within 2–5 minutes.

### Correction of Hypoglycemia and Hypocalcemia

If glucose estimation reveals hypoglycemia or if there is no facility to test blood sugar immediately, 2 mL/kg of 10% dextrose should be given as a bolus injection followed by a continuous infusion of dextrose at 6–8 mg/kg/min. If hypoglycemia has been treated or excluded as a cause of convulsions, the neonate should be screened for hypocalcemia (iCa is seen in most ABG). If however, it cannot be tested immediately, 2 mL/kg of 10% calcium gluconate IV diluted in distilled water over 10 minutes under strict cardiac monitoring, should be given. If ionized calcium levels are suggestive of hypocalcemia, the newborn should receive calcium gluconate at 8 mL/kg/day for 3 days. If seizures continue despite initial correction of hypocalcemia, serum magnesium should be tested. If hypomagnesemia is documented (serum Mg <1.6 mg/dL), 0.25 mL/kg of 50% magnesium sulfate should be given intramuscularly (IM) every 12 hourly for 3 doses.

### Antiepileptic Drug Therapy

Antiepileptic drug (AED) therapy should be given if seizures occur after correction of hypoglycemia or hypocalcemia. Antiepileptic drugs should be considered in the presence of even a single clinical seizure since clinical observations tend to grossly underestimate electrical seizures (diagnosed by EEG) and facilities for continuous EEG monitoring are not universally available. Phenobarbitone is the drug of choice in neonatal seizures. The issues related to AED are discussed briefly below.

#### Clinical versus Electrical Seizures

As per World Health Organization (WHO) recommendations, all clinically apparent seizures lasting for more than 3 minutes or brief

serial seizures are to be treated. If continuous EEG monitoring is available, all electrical seizures should be treated even in absence of clinically apparent seizures, especially if babies are paralyzed.

### Preferred First-Line AED for Neonatal Seizures

Commonly used first-line AEDs for treatment of neonatal seizures are phenobarbitone and phenytoin. Phenobarbitone has been used as first-line drug for neonatal seizures in loading dose of 20 mg/kg/dose. Though it is very commonly used, various trials have shown its limitation in control of seizures in neonatal period (efficacy has been reported from 44% to 72%).

### Preferred Second-Line Drug for a Newborn not Responding to First Dose of Phenobarbitone

Till more data is available phenobarbitone is the most preferred drug (further loading dose of 10 mg/kg/dose till cumulative dose 30 mg/kg is achieved). For children not responding to maximum tolerated doses of phenobarbitone, as per WHO, either phenytoin or benzodiazepine or lidocaine may be used as second-line AED. Role of levetiracetam needs to be aggressively evaluated, considering its wide therapeutic index. A recent pilot study from our institute demonstrated reasonable efficacy of levetiracetam as second-line drug.

- The Cochrane review found only one randomized controlled trial (RCT) that showed comparable seizure control rate with phenobarbital and phenytoin [relative risk (RR) 1.03, 95% confidence interval (CI) 0.96–1.62], controlling seizures in only half of cases.
- Based on the available evidence, the WHO guideline on neonatal seizures recommends phenobarbitone as the first-line agent for management of neonatal in doses of 20 mg/kg/dose IV dissolved in 1:10 dilution with normal saline slowly over 20 minutes (not faster than 1 mg/kg/min).
- The Cochrane review found one study that randomized infants who failed to respond to phenobarbital to receive either lidocaine or midazolam as second-line agents. There was a trend for lidocaine to be more effective in reducing seizure burden (RR 0.40 95% CI 0.14–1.17) but both groups had similarly poor long-term outcomes assessed at 1 year.
- Based on the available evidence, the WHO guidelines on neonatal seizures recommend either midazolam or lidocaine as the second-line AED in neonatal seizures.
- However, given the lack of robust evidence and constraints involved in providing respiratory support and/or cardiac monitoring in most neonatal units in India, it seems appropriate to use phenytoin or levetiracetam as the second-line agent in neonates with seizures.

**Table 2** provides a summary of AEDs and their dosages recommended for neonatal seizures. **Flow chart 1** provides an algorithm for management of neonatal seizures.

### End Point of Treatment

If facility for continuous EEG monitoring is not available, abolition of all clinical seizures should be the target till three drugs are used. One has to weigh the benefits of controlling all electrical or clinical seizures against risks with multiple antiepileptic drugs (AEDs). After use of three AEDs, not all twitch/movement should be treated. Further AED should be given only if seizures are associated with abnormality in heart rate or blood pressure. Even when continuous EEG monitoring is available, it may not be impossible to control all electrical seizures with currently available drugs.

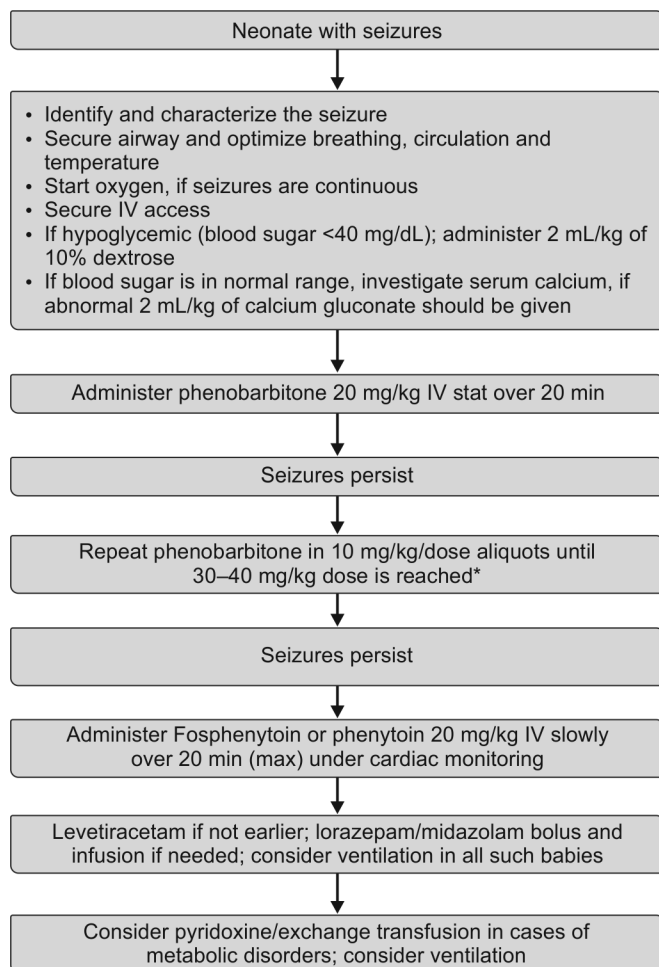

### Maintenance Dose of Antiepileptic Drugs

Traditionally, loading dose of AED has been followed by maintenance dose of AED to maintain the desired serum

**Table 2** Anticonvulsants used in neonatal period

Drugs	Doses	Possible adverse effects
Phenobarbitone	Loading at the rate of 20 mg/kg/dose followed by 10 mg/kg/dose IV till maximum 40 mg/kg/dose Maintenance dose: 3–5 mg/kg/day q 12–24 hourly IV/IM/PO	Hypertension, hypotension, respiratory depression and create brain death like state. Long-term effect on attention, memory and cognition has been postulated
Phenytoin	20 mg/kg, IV (0.5–1.0 mg/kg/min) IV Maintenance dose: 3–4 mg/kg/day q 12 hourly IV	Respiratory depression, hypotension or bradycardia or other cardiac abnormalities, avoid oral route due to poor bioavailability
Levetiracetam	Loading 30–60 mg/kg IV at the rate of 5 mg/kg/min. Maintenance dose: 10 mg/kg/dose q 8–12 hourly IV/PO	Safe drug, wide therapeutic index. Drug level monitoring not required
Lorazepam	0.05–0.10 mg/kg, IV over 5 min	Respiratory depression, apnea, and bradycardia
Midazolam	0.2 mg/kg, IV bolus; then, 0.1–0.4 mg/kg/hour	Advantage of less respiratory depression and sedation than lorazepam
Sodium valproate	20–25 mg/kg/dose IV followed by 5–10 mg/kg q 12 hourly IV/Oral	Hepatotoxicity, elevated blood ammonia levels
Lidocaine	4 mg/kg IV followed by infusion of 2 mg/kg/hour	Arrhythmia, hypotension and seizures
Paraldehyde	0.1–0.2 mL/kg/dose IM or 0.3 mL/kg/dose with coconut oil in 3:1 per rectal	Respiratory disturbance (pulmonary hemorrhage, pulmonary edema, hypotension), secondary to pulmonary excretion of paraldehyde
Pyridoxine	1 mL IM in both sides either in gluteal region or in anterolateral aspect of thigh	Hypotension, apnea
Topiramate	Initial dose and maintenance dose of approximately 3 mg/kg	Anorexia, weight loss, vomiting, diarrhea, acidosis
Bumetanide	Inhibits NKCC1 receptors (under trial)	

Abbreviation: NKCC1, sodium-potassium-chloride cotransporter.

**Flow chart 1** Algorithm for management of neonatal seizures

\* 30 mg/kg in perinatal asphyxia especially if no facility to monitor serum levels.

level and prevent recurrence of seizures for the duration. After the pathophysiology which caused seizures has been corrected or reverted, the AED can be gradually tapered and stopped. Duration of maintenance dose therapy has been under considerable scientific attention recently. Its duration has been significantly curtailed from months to weeks and now to a few days only. A recent trial from our institute on about 150 babies indicated that withholding maintenance altogether after control of seizures with only a single loading dose of phenobarbitone does not result in higher incidence of breakthrough seizures.

As per WHO guidelines, in neonates with normal neurological examination and/or normal EEG, consider stopping AED if baby is seizure free for more than 72 hours. The drugs can be reinstituted in case seizure recurs.

### Stopping Antiepileptic Drugs

No clear guidelines are available for weaning of AEDs after acute or chronic use. In acute stage, one can start weaning AED once no seizures are observed for at least 3–5 days. General consensus is to discontinue all medications at discharge if clinical examination is normal, irrespective of etiology and EEG. In patients on multiple AEDs, after a seizure free period of 48–72 hours, one should stop that drug first which is added last and stop the phenobarbitone in last. The seizure recurrence depends on three factors: (1) neurological examination, (2) cause of neonatal seizure and (3) EEG pattern. Protocol of stopping AED takes into account these three factors.

### Management of Neonatal Seizures in Primary Care Settings

Newborn presenting to a primary health center (PHC) or first referral unit (FRU) with seizures needs to be stabilized hemodynamically before referring to higher center. Temperature of the baby should be maintained by placing under radiant warmer (if available), intranasal oxygen should be started, the airway cleaned by suction and baby's neck be kept in slight extension. Initial steps are same as described earlier.

Check blood sugar if facility is available, else give 10% dextrose empirically at 2 mL/kg body weight (approximately 5 mL in term and 3 mL in preterm neonates). If seizure persists, intravenous (IV, if accessible) or intramuscular (IM) phenobarbitone is to be given at loading dose of 20 mg/kg body weight. If IM injection cannot be given for any reason, same dose can be given through nasogastric tube. First dose of antibiotic should be given before transport. After this, patient should be transported to higher center. During transportation, one should assure that TABC (temperature, airway, breathing and circulation) is maintained properly. The family needs to be counseled appropriately. Before transporting one should communicate with referral team for condition at referral availability of bed and medical personal at the receiving center. Transport should ideally be in transport ambulance vehicle with facilities of oxygen, IV fluids and resuscitation kit and a medical personal should accompany the baby.

## PROGNOSIS

Appropriate management and regular neurological assessment can prevent major neurodevelopmental sequelae such as motor deficits and mental retardation after neonatal seizures. Recurrent seizures may lead to specific learning difficulties or poor social adjustment, in late teenage years.

Good prognosis is associated with subarachnoid hemorrhage (SAH) and late onset hypocalcemia. Risk of subsequent epilepsy after neonatal seizures due to perinatal asphyxia is approximately 30–50%, and after seizures secondary to cortical dysgenesis, it is almost 100%. Major background disturbances such as burst suppression are highly predictive of poor outcome, particularly if they persist into the second week of life. Ictal patterns alone may not be as accurate for predicting outcome, unless they occur in high numbers, long durations, and multifocal distribution.

## PREVENTION

### Antenatal Strategies

Proper antenatal care including electronic fetal monitoring (EFM) during labor has shown to reduce incidence of neonatal seizures. Antenatal steroid given to mothers with threatened preterm deliveries has been shown to reduce intraventricular hemorrhage by almost 50%. Similarly, antenatal magnesium sulfate therapy in eclampsia mothers decreases risk of seizures in newborns (MAGPIE trial).

### Perinatal Strategies

Good neonatal resuscitation in first golden minute of birth in babies of birth asphyxia with or without meconium by reducing the duration of hypoxia and hypercapnea can be helpful in preventing seizures. One can minimize free radical neuronal

injury in asphyxiated babies by preventing hyperoxia and setting oxygen saturation target to 88–92%.

## Postnatal Strategies

Promotion of exclusive breastfeeding as it reduces incidence of sepsis and meningitis. Late onset hypocalcemia seizures can be reduced by exclusive breastfeeding rather than cow's milk. Screening for blood sugar levels and hematocrit in high-risk babies like premature, intrauterine growth retarded and infant of diabetic mothers can lead to early diagnosis of hypoglycemia and polycythemia, preventing neurological sequelae. Newborn screening for metabolic diseases may lead to early diagnosis and treatment of conditions like galactosemia.

### IN A NUTSHELL

1. Neonatal seizures are one of the major causes of neonatal mortality and morbidity, hence it has to be critically recognized, evaluated and treated.
2. All electrical seizures are to be treated and in absence of electrical seizure monitoring all clinical seizures should be treated.
3. Phenobarbitone is the first drug of choice in treatment of neonatal seizures.
4. Levetiracetam has upcoming role as second-line drug with good safety and efficacy profile.
5. Early stopping (48–72 hours) of AEDs is now advised as to prevent long-term side effects of these drugs.
6. Long-term prognosis of babies with neonatal seizures strongly depends on gestation age, etiology and interictal EEG pattern.
7. Parental counseling and regular neurodevelopmental screening has to be done in babies with neonatal seizures till the age of 2 years to prevent long-term abnormal neurological outcome.

## Chapter 16.2

# Hypoxic Ischemic Encephalopathy

B Vishnu Bhat, B Adhisivam

According to the WHO, perinatal asphyxia is defined as a *failure to initiate and sustain breathing at birth*. According to the American Academy of Pediatrics and ACOG, significant perinatal asphyxia is present when all of the following criteria are present: (1) profound metabolic or mixed acidemia (pH < 7) in umbilical cord blood, (2) persistence of low Apgar scores less than 3 for more than 5 minutes, (3) signs of neonatal neurologic dysfunction (e.g., seizures, encephalopathy, tone abnormalities), and (4) evidence of multiple organ involvement (such as that of kidneys, lungs, liver, heart and intestine). The associated dysfunction of the central nervous system (CNS) is referred to as hypoxic ischemic encephalopathy (HIE).

Every year, around 4 million babies die in the neonatal period (first 28 days of life) globally and asphyxia is one of the important direct causes accounting for 23% of these neonatal deaths. Among the survivors of asphyxia, cerebral palsy is a sequel which results in loss of an individual's productive capacity and may be a lifelong burden for the family and social institutions.

## EPIDEMIOLOGY

There is an estimated 0.7–1.2 million neonatal deaths annually across the world attributable to asphyxia. Nearly 99% of these deaths occur in developing countries and only 1% in developed countries. HIE occurs in 1.5 per 1,000 live full-term births. About 15–20% of affected newborns die in the postnatal period, and in addition 25% will continue to have childhood disabilities. Moreover HIE is a major problem for the individual, family, and society accounting for 15–28% of children with cerebral palsy and 25% of all cases of developmental delay. The prevalence of cerebral palsy among term deliveries has remained the same, approximating 2 per 1,000 livebirths despite significant advances in perinatal care. Long-term outcome is found to depend on the severity of neonatal encephalopathy (NE). According to National Neonatal Perinatal Database (2003), Apgar score less than 7 at 1 minute (including moderate and severe asphyxia) was documented in 9% of all intramural deliveries and 2.5% babies had Apgar scores less than 7 at 5 minutes of age. Twenty percent of all neonatal deaths were due to perinatal asphyxia. Manifestations of HIE were seen in approximately 1.5% of all babies. Perinatal asphyxia was also the most common cause for stillbirths accounting for one-third of all such cases.

## ETIOLOGY

It is practically impossible to ascertain the exact time of the hypoxic insult sustained by a newborn unless some convincing evidence is available. Some of the common causes for HIE are listed in **Table 1**. Clinical presentation of NE of varying etiologies can overlap and therefore its clinical presentation alone makes it difficult to identify the etiology. It is important to exclude other causes of NE in the absence of risk factors for perinatal asphyxia.

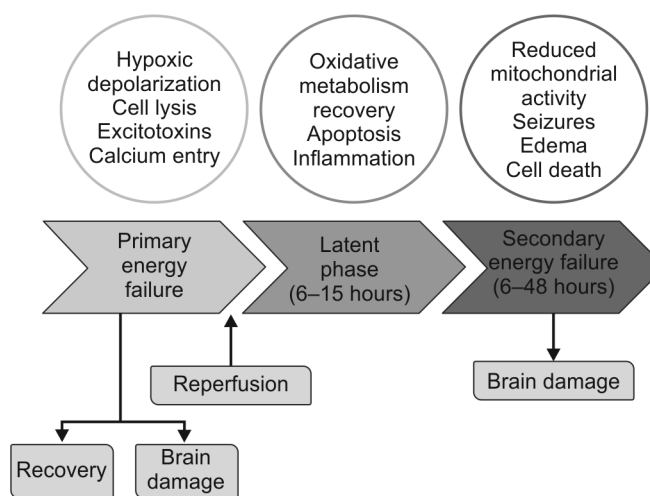

## PATHOPHYSIOLOGY

Hypoxic ischemic encephalopathy is not a single *event* but is rather a continuum starting from the time of insult. Two distinct episodes of neuronal impairment are known to occur during this time. The

immediate (primary) hypoxic insult is followed by a latent period of recovery which lasts for almost 6 hours. Subsequently there is a longer and profound period of secondary neuronal damage due to the release of chemical mediators. Neural tissue may die initially during the actual ischemic or asphyxial event. Several neurons however recover at least partially from the primary insult in a *latent* phase but die hours or even days later (secondary or delayed cell death) (**Fig. 1**).

**Table 1** Etiology of hypoxic ischemic encephalopathy

Maternal	Uteroplacental	Fetal
Cardiac arrest	Placental abruption	Fetomaternal hemorrhage
Asphyxiation	Cord prolapse	Twin to twin transfusion
Severe anaphylaxis	Uterine rupture	Severe isoimmune hemolytic disease
Status epilepticus	Hyperstimulation with oxytocic agents	Cardiac arrhythmia
Hypovolemic shock		

**Figure 1** Pathophysiology of hypoxic ischemic encephalopathy

The pathophysiology of HIE includes two phases—(1) *primary* and (2) *secondary* energy failure based on the cerebral energy state. Cerebral blood flow and oxygen substrates are decreased in primary energy failure. Reduction in adenosine triphosphate (ATP) and other phosphorylated compounds like phosphocreatine and significant tissue acidosis are important features during this phase. An *excitotoxic-oxidative cascade* characterized by excessive stimulation of neurotransmitter receptors and membrane depolarization causing an increase in intracellular calcium and osmotic dysregulation is also observed. Intracellular calcium activates neuronal nitric oxide synthase, leading to the release of the oxygen-free radical nitric oxide, which in turn affects mitochondrial respiration (**Flow chart 1**). These signals from damaged mitochondria lead to apoptosis or programmed cell death till energy supplies are available. However, cessation of these energy supplies results in cell necrosis. Activation of caspase enzyme system can also trigger apoptosis. Resolution of hypoxia can reverse the decrease in ATP and intracellular pH and enhances recycling of neurotransmitters. In case of prolonged and severe insult, the initial cascade of events will cause a second interval of energy failure in the mitochondria.

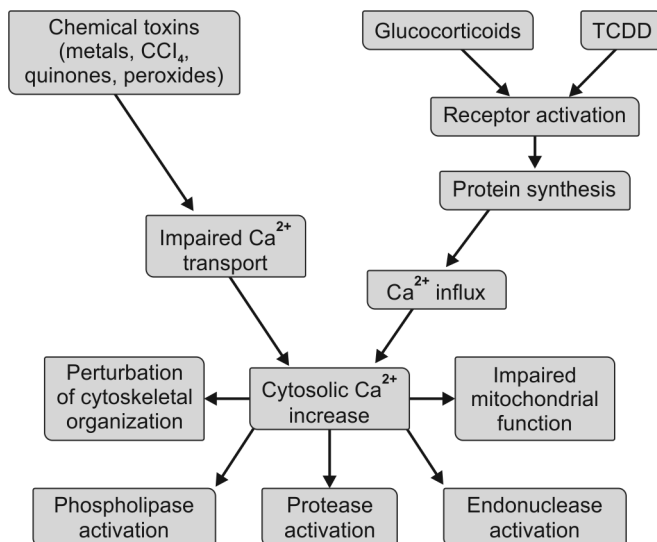

during which time the brain is depleted of ATP. This secondary energy failure differs from the primary in that the decline in the levels of phosphorylated compounds is not accompanied by brain acidosis. The secondary energy failure is characterized by continuing excitotoxic-oxidation cascade, apoptosis, inflammation and altered growth factor levels and protein synthesis (**Table 2**). The interval between primary and secondary energy failure represents a latent phase that corresponds to a therapeutic window (approximately 6 hours). Research has shown that cell death in the brain exposed to hypoxic insult is delayed over several days to weeks and apoptosis and necrosis continue depending on the region and severity of the injury. Gestational age has a role in the susceptibility of the brain to hypoxic damage. In term neonates, the gray matter is primarily affected (selective neuronal necrosis), while in the preterm it is the white matter leading to periventricular leukomalacia. The other factors which contribute to the degree of damage include cellular susceptibility, watershed areas, regional metabolic rates and degree of asphyxia.

### Oxidative Stress and DNA Damage in Asphyxia

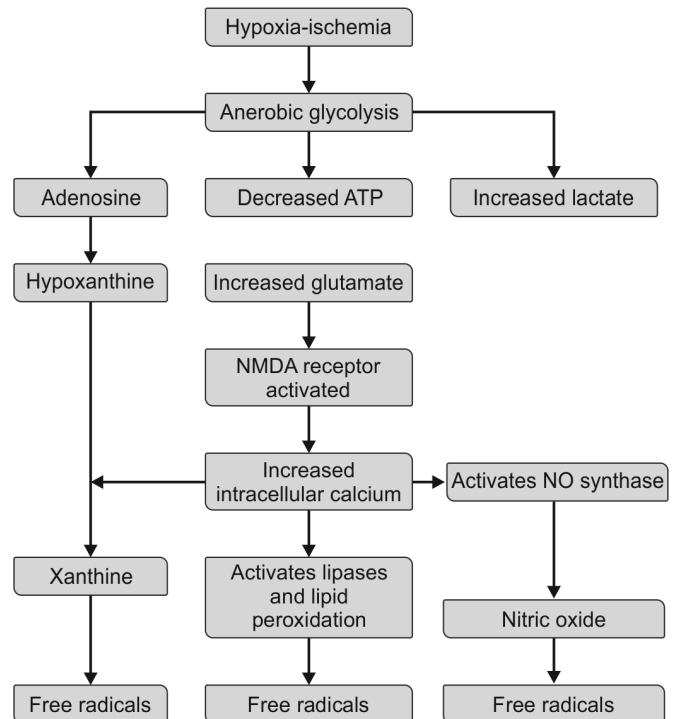

There are three important pathways that lead to free radical production. First one is *Fenton reaction*. During hypoxic ischemia, protein-bound iron is liberated from its binding proteins in the neuronal and microglial cells. Non-protein bound iron (NPBI) or free iron will accumulate during hypoxic ischemia. Upon

reperfusion and reoxygenation, NPBI will react with hydrogen peroxide to form the toxic hydroxyl-free radical. NPBI has been related to excessive brain damage in the immediate posthypoxic ischemia period. Second, the activation of neuronal and inducible nitric oxide synthase (nNOS and iNOS respectively) leads to the generation of the nitric oxide radical (NO•), which reacts with superoxide to form the toxic peroxynitrite (ONOO•). Peroxynitrite and reactive oxygen species cause DNA damage and cell death. Finally, hypoxanthine, accumulated during the hypoxic ischemic episode as a degradation product of ATP, is metabolized to uric acid by xanthine oxidase (XO). This reaction gives rise to further formation of superoxide radicals (**Flow chart 2**). These toxic-free radicals contribute substantially to reperfusion injury of the brain after severe hypoxia-ischemia. Neonatal brain is more susceptible to oxidative stress because of low concentrations of antioxidants, a high consumption of oxygen when transitioning from fetal to neonatal life and presence of high concentrations of unsaturated fatty acids that break down to form more oxygen-free radicals.

**Flow chart 1** Pathophysiology of hypoxic ischemic encephalopathy—key events

**Flow chart 2** Free radicals production in hypoxic ischemic encephalopathy

**Table 2** Characteristics of energy failures related to hypoxic ischemic encephalopathy

Primary energy failure	Secondary energy failure
Decrease in cerebral blood flow, oxygen substrates and ATP	Continuing of excitotoxic-oxidative cascade
Excitotoxic-oxidative cascade	Activation of microglia— inflammatory response
Loss of ionic homeostasis across membranes	Activation of caspase proteins
Entry of intracellular calcium	Reduction in levels of growth factors, protein synthesis
Mitochondrial disruption	Continuing apoptosis and necrosis
Brain acidosis	
Apoptosis and necrosis	

## CLINICAL FEATURES

The important CNS clinical features of HIE include altered level of sensorium, seizures and tone abnormalities. Their appearance is variable depending on the progression of energy failure and severity of insult and the usual time frame of these clinical features are depicted in **Figure 2**. For quantifying the severity of HIE, Sarnat and Sarnat classification is commonly used while Levene's classification is also helpful (**Tables 3 and 4**). Though the CNS features are sine qua non of HIE, all other organ systems including the kidney and heart are also affected in variable proportions depending on the disease severity and quality of care (**Table 5**). All organs in the body are at risk of cell injury and death when subjected to hypoxia. Certain organs are more susceptible to injury than others, and distinct physiological reflexes attempt to protect the vital organs from damage (i.e., diving reflex).

Acute kidney injury (AKI) is a common occurrence in infants with NE, with a reported incidence of 50–72%. Most of these studies are small and employ varying definitions for AKI based on elevation of serum creatinine, oliguria, decreased glomerular filtration rate and presence of hematuria and proteinuria. Nevertheless, these studies emphasize the frequency of AKI complicating NE and underline the uncertainty surrounding the precise and early diagnosis of AKI in critically ill neonates. The majority of AKI following perinatal hypoxia-ischemia is prerenal in origin and often nonoliguric.

Cardiovascular dysfunction forms part of the clinical spectrum of multiorgan dysfunction, which is very common when a term newborn sustains a hypoxic ischemic insult. The reported incidence of cardiovascular dysfunction ranges from 29% to 78%. Oxygen deprivation secondary to a hypoxic ischemic event is thought to cause myocardial damage with subsequent development of a low cardiac output, decreased myocardial contractility, systemic hypotension and pulmonary hypertension.

## DIFFERENTIAL DIAGNOSES

History of prolonged and difficult labor coupled with need for significant resuscitation, low apgar scores, altered sensorium and early onset seizures will usually point toward HIE. However, other differential diagnoses, like inborn errors of metabolism, neuromuscular disorders, developmental defects of brain and sepsis, should be kept in mind as their clinical features may overlap with HIE. It is not uncommon to find meconium aspiration syndrome and sepsis associated with HIE in term and preterm babies respectively.

## APPROACH TO DIAGNOSIS

A detailed history regarding the pregnancy and intrapartum period reflecting events leading to compromised blood or oxygen supply to the fetus should be obtained. These events include placental abruption, amniotic fluid embolism, tight nuchal cord, cord prolapse/avulsion, maternal hemorrhage (placental abruption/accreta), trauma or cardiorespiratory arrest, uterine rupture, and acute severe and sustained fetal decelerations. A history of maternal elevation of temperature increases the risk of NE. A careful neurologic examination needs to be performed to diagnose encephalopathy.

## INVESTIGATIONS

Apart from the standard investigations for supportive care, the following may be helpful in the management and prognosis of HIE.

## Electroencephalography

Electroencephalography (EEG) is not indicated routinely in all asphyxiated babies. However, it helps in the diagnosis and management of seizures and prognosticating the babies for long-term outcomes. The prognosis is likely to be poor if the EEG shows long periods of inactivity (> 10 sec); brief period of bursts (< 6 sec) with small amplitude bursts; interhemispheric asymmetry and asynchrony; or isoelectric and low voltage (< 5 mV).

## Amplitude-integrated Electroencephalography

Amplitude-integrated electroencephalography (aEEG) can be performed on continuous basis in neonatal intensive-care unit (NICU) and the following abnormalities would indicate poor prognosis: wide fluctuations in the amplitude with the baseline voltages dropping to near zero; peak amplitudes under 5 mV; and seizure spikes. While a normal aEEG may not necessarily mean that the brain is normal, a severe or moderately severe aEEG abnormality may indicate brain injury and poor outcome.

## Cranial Ultrasound

Cranial ultrasound (US) is not good for detecting changes of HIE in the term babies. However, hypoechoic areas can be seen in very severe cases (having large areas of infraction). In preterm babies, US can pick up periventricular leukomalacia and intraventricular-periventricular hemorrhage by serial cranial US during the first week of life.

## Computed Tomography

Computed tomography (CT) is more useful after a traumatic delivery and suspected of having an extra-axial hemorrhage.

## Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is preferred over CT as it has a greater interobserver agreement and no radiation exposure. Abnormalities of thalami and basal ganglia in term infants and that of white and gray matter at term equivalent age in preterm infants and an altered signal at the level of the posterior limb of the internal capsule are strong predictors of subsequent risk of poor neurodevelopmental outcome. The second most common pattern of injury is injury to the watershed regions. Diffusion weighted MRI can pick up abnormalities within days after birth, though more pronounced in later during the first week.

## MANAGEMENT

The management of neonates with HIE was limited to supportive intensive care, including resuscitation in the delivery room followed by stabilization of hemodynamic and pulmonary disturbances (hypotension, metabolic acidosis, and hypoventilation), correction of metabolic disturbances (glucose, calcium, magnesium, and electrolytes), treatment of seizures, and monitoring for multiorgan dysfunction. These general guidelines for supportive care are outlined in **Table 6**. Newer approaches are discussed below:

## Therapeutic Hypothermia

Therapeutic hypothermia (TH) has been proven to be effective in reducing morbidity associated with HIE and has become the standard of care for HIE in developed countries. However, in underdeveloped and transitional countries where the problem is more common, therapeutic cooling is still in the nascent phase. There are several reasons for this problem in resource restricted settings including the cost of devices needed for providing TH. Two recent systematic reviews on the efficacy and safety of TH in low- and-middle-income resource settings have been unable to

Birth–12 hours	Depressed level of alertness, periodic breathing or respiratory failure, intact pupillary and oculomotor responses, hypotonia, seizures
12–24 hours	Change in level of alertness, seizures, apneic spells, jitteriness, weakness in proximal limbs, upper > lower (term), lower > upper (preterm)
24–72 hours	Stupor or coma, respiratory arrest, brain stem pupillary and oculomotor disturbances, catastrophic deterioration with severe intraventricular hemorrhage and periventricular hemorrhagic infarction (premature)
> 72 hours	Persistent yet diminishing stupor, disturbed sucking, swallowing, gag and tongue movements, hypotonia > hypertonia, limb weakness

**Figure 2** Hypoxic ischemic encephalopathy—clinical features**Table 3** Sarnat and Sarnat classification of hypoxic ischemic encephalopathy

	<i>Stage 1</i>	<i>Stage 2</i>	<i>Stage 3</i>
Level of consciousness	Hyperalert	Lethargic or obtunded	Stuporous
Neuromuscular control			
Muscle tone	Normal	Mild hypotonia	Flaccid
Posture	Mild distal flexion	Strong distal flexion	Intermittent decerebration
Stretch reflexes	Overactive	Overactive	Decreased or absent
Segmental myoclonus	Present	Present	Absent
Complex reflexes			
Suck	Weak	Weak or absent	Absent
Moro	Strong; low threshold	Weak; incomplete; high threshold	Absent
Oculo-vestibular	Normal	Overactive	Weak or absent
Tonic neck	Slight	Strong	Absent
Autonomic function	Generalized sympathetic	Generalized parasympathetic	Both systems decreased
Pupils	Mydriasis	Miosis	Variable; often unequal; poor light reflex
Heart rate	Tachycardia	Bradycardia	Variable
Bronchial and salivary secretions	Spars	Profuse	Variable
Gastrointestinal motility	Normal or decreased	Increased; diarrhea	Variable
Seizures	None	Common; focal or multifocal	Uncommon (excluding decerebration)
Electroencephalogram findings	Normal (awake)	Early low-voltage continuous delta and theta Later, periodic pattern (awake) Seizures: Focal 1–1.5 Hz spike and wave	<i>Early:</i> Periodic pattern with isopotential phases <i>Later:</i> Totally isopotential
Duration	Less than 24 hours	2–14 days	Hours to weeks

**Table 4** Levene's classification of hypoxic ischemic encephalopathy

<i>Feature</i>	<i>Mild</i>	<i>Moderate</i>	<i>Severe</i>
Consciousness	Irritable	Lethargy	Comatose
Tone	Hypotonia	Marked hypotonia	Severe hypotonia
Seizures	No	Yes	Prolonged
Sucking/respiration	Poor suck	Unable to suck	Unable to sustain spontaneous respiration

generate unequivocal evidence of its benefits in low- and middle-income countries.

Therapeutic hypothermia is neuroprotective by inhibiting many steps in the excitotoxic-oxidative cascade, including

**Table 5** Organ system dysfunction in perinatal asphyxia

CNS	Hypoxic ischemic encephalopathy, intracranial hemorrhage, seizures, long-term neurological sequelae
Cardiac	Myocardial dysfunction, valvular dysfunction, rhythm abnormalities, congestive cardiac failure
Renal	Hematuria, acute tubular necrosis, renal vein thrombosis
Pulmonary	Delayed adaptation, respiratory failure, meconium aspiration, surfactant depletion, primary pulmonary hypertension
GI tract	Necrotizing enterocolitis, hepatic dysfunction
Hematological	Thrombocytopenia, coagulation abnormalities
Metabolic	Acidosis, hypoglycemia, hypocalcemia, hyponatremia

**Table 6** Guidelines for management of hypoxic ischemic encephalopathy

<ul style="list-style-type: none"> <li>Follow neonatal resuscitation program (NRP) guidelines</li> </ul>
<ul style="list-style-type: none"> <li>Establish adequate ventilation/oxygenation and circulation</li> </ul>
<ul style="list-style-type: none"> <li>Oxygen—For babies born at term, it is best to begin resuscitation with room air rather than 100% oxygen. If despite effective ventilation there is no increase in heart rate or if oxygenation remains unacceptable, use of higher concentration of oxygen should be considered</li> </ul>
<ul style="list-style-type: none"> <li>Ventilation—Avoid hypocapnia or hypercapnia</li> </ul>
<ul style="list-style-type: none"> <li>Maintain normal temperature—Avoid hyperthermia</li> </ul>
<ul style="list-style-type: none"> <li>Maintain normal tissue perfusion</li> </ul>
<ul style="list-style-type: none"> <li>Glucose—Correct hypoglycemia</li> </ul>
<ul style="list-style-type: none"> <li>Treat seizures if present</li> </ul>
<ul style="list-style-type: none"> <li>Maintain normal hematocrit and correct metabolic acidosis</li> </ul>
<ul style="list-style-type: none"> <li>Therapeutic hypothermia if indicated</li> </ul>

inhibiting the increase in brain lactic acid, glutamate, and nitric oxide concentrations and epileptic activity (**Flow chart 3**). Moreover, TH inhibits protease activation, mitochondrial failure, free radical damage, lipid peroxidation and inflammation. TH has been shown to decrease brain energy use, prolong the latent phase, reduce infarct size, decrease neuronal cell loss, retain sensory motor function, and preserve hippocampal structures. Prolonging TH from 24 hours to 72 hours after hypoxia-ischemia attenuates brain damage and improves behavioral performance. The sooner hypothermia can be initiated; the more likely it is to be successful. Hypothermia is most effective when administered during the latent phase of the injury, before the onset of the secondary phase of energy failure (6 hours). The degree of neuroprotection progressively declines if cooling is initiated more than a few hours after insult. Moderate hypothermia at brain temperatures of 32–34°C initiated immediately or within a few hours after reperfusion and continued for 24–72 hours has been shown to favorably affect outcome in newborn and adult animals.

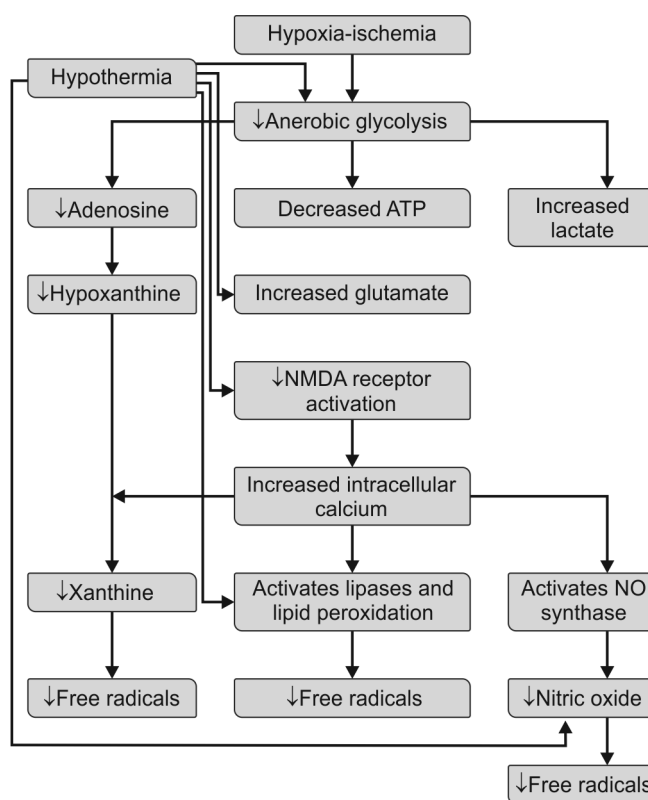

There are several modes of achieving TH. *Selective head cooling* is attractive, because it can provide adequate neuroprotection with minimal risk of systemic adverse effects, but it is associated with differential gradients within the brain and does not correlate well with the core body temperature. In contrast, *total body cooling* is more likely to be associated with adverse effects but causes fewer gradients within the brain and it correlates well with the core body temperature. Manually controlled cooling systems are associated with greater variability in temperature compared with servo-controlled systems. A manual mattress often causes initial overcooling. It is unknown whether large variation in temperature adversely affects the neuroprotection of TH.

### Prerequisites for Initiating Therapeutic Hypothermia

Strict guidelines and adequate supervision are essential for implementing TH for HIE. Monitoring facilities of the NICU, trained personnel and a backup system to manage complications should be in place. Inadvertent or accidental excessive hypothermia should be a *never event* in the NICU, especially in low-birthweight infants. The minimum prerequisites (4Ps) for an optimum TH implementation are described in **Table 7**.

### Problems in Instituting Therapeutic Hypothermia in India

In a review on ethical and practical issues relating to the global use of TH for perinatal encephalopathy, Wilkinson et al. have summarized the following points which are pertinent to Indian scenario. In resource restricted settings, brain damage due to perinatal asphyxia may be more established owing to maternal malnutrition, intrauterine growth restriction, obstructed labor and suboptimal obstetric/neonatal care. More than two-thirds of the deliveries in India happen outside

**Flow chart 3** Therapeutic hypothermia—possible mechanisms**Table 7** Prerequisites for an optimum therapeutic hypothermia implementation

Place	Personnel	Infrastructure	Protocols
Level III NICU	Trained neonatologist and nursing staff with round the clock monitoring	<ul style="list-style-type: none"> <li>Radiant warmer</li> <li>Cooling device</li> <li>Rectal and surface probes for temperature monitoring</li> <li>Multiparametric monitors (temperature, NIBP, SPO<sub>2</sub>, heart rate, respiratory rate)</li> <li>ABG machine</li> <li>Mechanical ventilator</li> <li>Glucometer</li> <li>aEEG (desirable)</li> <li>MRI (desirable)</li> </ul>	<ul style="list-style-type: none"> <li>Timely identification of HIE</li> <li>Ensuring TH for eligible infants within 6 hours of birth</li> <li>Evidence-based standard protocol for providing and monitoring TH</li> <li>Standardized neurodevelopmental follow-up</li> <li>Continuing staff education</li> </ul>

the hospital. The usefulness of cooling may be reduced if there is a high incidence of pre-existing brain damage or if the therapeutic window has elapsed. By the time the neonates are admitted in the neonatal unit, the secondary surge of neuronal death related to secondary energy failure may have already happened.

In several areas, HIV infection and puerperal sepsis are relatively common among mothers. Perinatal asphyxia may also coexist with neonatal sepsis, and it may be challenging to differentiate both the conditions at birth. Exclusion of infected infants is unlikely to be realistic and core temperature reduction may result in neutrophil compromise, which can worsen sepsis and pneumonia. This may partially explain the relationship between hypothermia and neonatal death in developing countries. Accidental hypothermia is witnessed in many asphyxiated infants in developing countries due to a number of factors including home birth, lack of basic neonatal care and overhead radiant warmers. Accidental hypothermia must be differentiated from TH and may dilute the benefit of TH in the standard care group in clinical research. Excessive cooling or *overcooling* is commonly associated with *inadequately controlled* cooling which usually happens during transport of very ill asphyxiated infants. In low-resource settings, the mandatory measuring of core body temperature may not always be practical when practicing TH. The adverse effects associated with TH are summarized in **Table 8**.

### Newer Therapies

The understanding of the differential responses to hypoxia-ischemia as an initial insult leading to cellular degeneration in brain has opened the way to develop new pharmacologic and therapeutic approaches. Due to the complex pathophysiology, therapies can target early pathways such as oxidative stress, inflammation and apoptosis or delayed pathways such as the deprivation of growth factors and cell death. Pharmacological interventions should start at different points of time according to their mechanisms of action (**Table 9**). The association of moderate hypothermia with neuroprotective drugs may decrease cell injury and optimize endogenous repair.

### Biomarkers

Biomarkers of neonatal HIE with good potential clinical applications include neuron-specific enolase, glial fibrillary acidic protein, brain-derived neurotrophic factor, and S100 $\beta$ . Serum and

urinary neutrophil gelatinase-associated lipocalin (NGAL) and urinary cystatin C (CysC) are early predictors of AKI secondary to HIE. Troponin-T and troponin-I are sensitive markers of myocardial injury following a perinatal hypoxic ischemic insult and may help predict severity of neonatal hypoxic ischemia and mortality. These findings are promising and open up the possibility of biomarkers playing a significant role in the early diagnosis and treatment of HIE and its complications.

### OUTCOME/PROGNOSTIC FACTORS

Prognosis of HIE can be made using the duration of the abnormal neurological symptoms and aEEG/conventional EEG changes. Infants who do not progress to Sarnat stage 3 and who have clinical signs of moderate encephalopathy for less than 5 days generally have a normal outcome. Persistence of Sarnat stage 2 symptoms for more than 7 days or abnormal cerebral background activity on aEEG/conventional EEG is frequently associated with later neurologic impairments. According to Murray et al., normal or mildly abnormal video EEG results within 6 hours after birth were associated with normal neurodevelopmental outcomes at 24 months of age. In contrast, clinical factors, such as more severe grade of encephalopathy, a higher number of neonatal seizures, requirement of more than one anticonvulsant medication, diffuse abnormalities on radiologic imaging, and abnormal findings on neurologic examination at discharge, are significantly associated with poor neurologic outcome by 2 years of age in infants with HIE. A recent systematic review from Netherlands revealed that aEEG, EEG, visual evoked potentials, diffusion weighted and conventional MRI had good prognostic value in HIE.

### PREVENTION

The best way to prevent HIE is to eliminate asphyxia during pregnancy and delivery. Awareness of HIE risk factors can help parents and medical personnel prevent this condition. HIE can be prevented by a multipronged approach involving all stake holders. Identifying high-risk cases and eliminating risk factors (treating maternal anemia, infections and malnutrition), early referral of high-risk patients to specialized birth centers, improving antenatal care, training health personnel in assessing and resuscitating newborn babies and developing appropriate transport systems for pregnant women and sick newborn babies are likely to decrease the incidence of HIE. Optimal antenatal, intrapartum, and postnatal care will save millions of newborn lives and also prevent HIE.

**Table 8** Complications of therapeutic hypothermia

• Skin erythema
• Sclerema and subcutaneous fat necrosis
• Pulmonary hemorrhage
• Pulmonary vasoconstriction
• Increased risk of infections
• Disseminated intravascular coagulation
• Increased blood viscosity—hemoconcentration
• Hypoglycemia
• Acid-base and electrolyte disturbances
• Hypotension—marked decrease in myocardial contractility and cardiac output in experimental animal models
• Bradycardia and other cardiac arrhythmia, sudden cardiac arrest

**Table 9** Newer therapies for hypoxic ischemic encephalopathy

Target pathway/area	Agent/therapy
Oxidative stress/excitotoxic damage	Melatonin, allopurinol, statins
Reperfusion	Magnesium, xenon, argon, deferoxamine, melatonin, cannabinoids
Inflammation/apoptosis	N-acetyl cysteine, melatonin, erythropoietin, iminobiotin
Downregulation of trophic factors	Erythropoietin
Cell death	Stem cells

### IN A NUTSHELL

1. Hypoxic ischemic encephalopathy is a complex process evolving over hours to days providing a unique window of opportunity for neuroprotective treatment interventions.
2. Advances in neuroimaging, brain monitoring techniques, and tissue biomarkers have improved the ability to diagnose, monitor, and care for newborn with HIE as well as predict their outcome.
3. Therapeutic hypothermia is the most promising neuroprotective intervention to date for infants with moderate to severe HIE.
4. Challenges remain in early identification of infants at risk for HIE, determination of timing and extent of hypoxic ischemic brain injury, as well as optimal management and treatment duration.

## Chapter 16.3

# Intraventricular Hemorrhage and White Matter Injury

Shamik Trivedi, Amit M Mathur

Improved survival of very low birthweight (VLBW) (weight  $\leq 1,500$  g) neonates in the setting of only a slight decline in the rate of preterm birth has resulted in more premature infants (50% of VLBW) surviving with significant neurodevelopmental disability in cognitive, behavioral, social and motor domains, neurological consequences of intraventricular hemorrhage (IVH), cerebellar hemorrhage, and white matter injury (WMI). Neonatal units across the Indian subcontinent are seeing a higher number of extremely low birthweight (ELBW) (weight  $< 1,000$  g) admissions and continued success in survival. In one level III unit in Pune, India, ELBW neonates made up 4.8% of the whole neonatal intensive-care unit (NICU) population with a survival rate of 55.8%, which has been seen in other units across the country as well.

Intraventricular hemorrhage is an entity primarily seen in the preterm neonate; however, term neonates are affected as well. Globally, IVH continues to significantly impact morbidity and mortality in the VLBW and ELBW population. Complications of severe IVH such as posthemorrhagic ventricular dilatation (PHVD) and WMI [also referred to as periventricular leukomalacia (PVL)] are associated with a higher risk of developing neurologic sequelae. WMI is the leading cause of cerebral palsy and other motor or cognitive developmental abnormalities in the preterm infant.

## EPIDEMIOLOGY

Primarily due to the advent of antenatal corticosteroid administration and improvement in delivery of neonatal care, the incidence of IVH has declined over the past three decades worldwide. In the USA, the incidence of IVH (Papile classification—any grade) in VLBW infants is between 20% and 25%. The incidence of periventricular hemorrhagic infarction (PVHI or Grade IV IVH) is between 5% and 11% in this population. In a prospective observational study conducted at a level III NICU in Pune, India; the incidence of severe (Grade III or IV) IVH in the ELBW population was 11.5%.

The incidence of IVH is inversely proportional to birthweight and gestational age of the neonate. In ELBW infants, the incidence is 50–60% in comparison to 20–25% in VLBW infants. In regards to gestational age, IVH rates decreased 3.5% with each added week of gestation as illustrated by a population-based study of 2,896 premature infants ( $< 32$  weeks of gestation) in Switzerland using the Swiss Neonatal Network Database. In term babies, the incidence of IVH is approximately 4%.

White matter injury is the predominant brain injury of the VLBW neonate with an overall incidence of 50% in population studies conducted in the US and is more prevalent than PVHI (5–11%) in this population.

## ETIOLOGY

In the preterm neonate, IVH occurs predominately in the subependymal germinal matrix. The *germinal matrix*, a highly cellular network of vascularized tissue primarily located in the lateral ventricle, is the site of proliferating neuronal and glial

precursors that develop into oligodendrocytes and astrocytes. The density of the vasculature is the largest in the germinal matrix. It is most prominent between 24 weeks and 34 weeks of gestation initially at the body of the caudate nucleus and by 28–32 weeks over the head of the caudate nucleus posterior to the foramen of Monro. The size of the germinal matrix decreases with advancing gestational age and is rarely seen beyond 35 weeks of postmenstrual age (PMA). The vascular system in preterm infants is fragile due to an immature support structure. The support structure consists of endothelial tight junctions, astrocyte end-feet, basement membrane and pericytes. Astrocyte end-feet surround the cerebral vascular providing structural integrity with glial fibrillary acidic protein (GFAP). In preterm infants, GFAP astrocyte end-feet are less prevalent in the germinal matrix compared to the cerebral cortex. Pericytes provide structural integrity to the capillaries, venules, and arterioles. Similar to astrocyte end-feet, pericytes are not abundant in the germinal matrix. In addition, impaired autoregulation of cerebral blood flow leads to a *pressure passive state* and altered flow. These two factors play a key role in the development of an IVH (see pathogenesis section).

The etiology of WMI is complex and not completely understood but involves ischemia, inflammatory, excitotoxic and oxidative stress.

## Timing

In preterm neonates, most IVH occur in the first week of life with 50% of bleeds occurring in the first 24 hours and 90% by 96 hours of life. In a study conducted at a single center in the US consisting of 1,105 ELBW neonates, 40% of the 265 infants with IVH developed the bleed within the first 5 hours. Extension of existing bleeds usually occurs within 3–5 days after the initial hemorrhage.

## Location

The majority of IVH in term infants occur due to bleeding in the *choroid plexus*, thought to be the case 35% of the time. Germinal matrix hemorrhage can be seen in about 3–4% of term infants, localized in the region of the thalamo-caudate groove, where residual subependymal germinal matrix hemorrhage remains (**Fig. 1**). WMI can be both focal and diffuse. The areas commonly affected by focal necrosis are around the foramen of Monro and the peritrigonal area of the lateral ventricles.

## The Injury

*Focal injury* can be macroscopic or microscopic necrosis in the deep periventricular white matter. Macroscopic necrosis with loss of cellular elements develops over weeks into cystic lesions seen on ultrasound (cystic WMI). Microscopic necrosis, also known as noncystic WMI, also evolves over weeks developing into glial scars that are not readily seen on cranial ultrasound (CUS). Cystic WMI is seen in approximately 5% of VLBW neonates and has decreased in prevalence over the years (**Fig. 2**). *Diffuse injury* to white matter precursor cells (OL-1 stage-pre-oligodendroglial cell) is mediated by excitotoxic, inflammatory and oxidative mechanisms. This injury results in not only a decrease in number of surviving preoligodendroglial cells but also a maturational arrest in the remaining cells due to accumulation of hyaluronic acid. Thus, these remaining cells do not mature effectively into myelin producing oligodendroglial cells thereby affecting neuronal signaling. The neuronal or axonal injury accompanying WMI affects the cerebellar white matter, thalamus, basal ganglia, cerebral cortex, and brain stem (**Fig. 3**). Axonal growth is prominent in the premature period and mature oligodendrocytes are necessary for effective axonal growth and connectivity.

**Figure 2** Coronal cranial ultrasound demonstrating bilateral cystic white matter injury (arrows) in the anterior

## PATHOGENESIS/PATHOPHYSIOLOGY

The vascular bed supplying the germinal matrix is a rich network of arteries, veins, and capillaries. The arterial supply is from the main branches of the anterior cerebral artery, middle cerebral artery, and anterior choroidal artery. The terminal branches near the germinal matrix are in a watershed zone predisposing it to ischemic or reperfusion injury. As the fetus matures, so does the capillary network. During early gestation, the network is fragile with thin, delicate, and immature walls without the support of a basement membrane. The preterm neonate has limited ability in autoregulating cerebral blood flow producing a *pressure passive state*. Using radioactive xenon tracer and near infrared spectroscopy (NIRS), studies show that systemic blood pressure and cerebral blood flow are linear in relation. A change in systemic blood pressure directly leads to alteration in cerebral blood flow. Lack of blood flow in the immature germinal matrix vessels leads to cell death, breakdown of the vessel wall, and eventual bleeding. As the bleeding in the germinal matrix expands, it has the potential to rupture through the ependyma into the lateral ventricle producing an IVH.

Ventricular blood flows through the drainage system reaching the foramina of Magendie and Luschka and collecting in the basilar cisterns in the posterior fossa. Clot formation most often occurs at the aqueduct of Sylvius near the level of the arachnoid villi. The vascular network supplying the germinal matrix is continuous with a well-developed venous system. The smaller tributaries drain into the terminal vein, coursing alongside the germinal matrix terminating in the vein of Galen. This close relationship between vascular systems plays a key role in development of PHVI. As the ventricle fills with blood or clot, the venous drainage of the periventricular parenchyma is impeded resulting in venous congestion.

Many of the pathogenic factors seen in preterm infants also apply to term infants. Three causes seen primarily in term infants are: (1) birth trauma, (2) coagulopathy, and (3) cerebral sinovenous thrombosis. The exact relationship between trauma and development of an IVH is not fully understood. Currently, the leading theory relates to factors that increase cerebral venous pressure. Coagulopathy is more prevalent in term infants with IVH. Based on case series reports, 40% of term infants with IVH were noted to be in a hypercoagulable state or in disseminated intravascular coagulopathy (DIC). Related to coagulopathy, recent data using

**Figure 3** A T2 weighted MRI image demonstrating diffuse high signal intensity in the white matter (arrow)

CT and MRI scans show the significance of cerebral sinovenous thrombosis in the pathogenesis of IVH in term newborns.

White matter injury occurs in areas of arterial watershed zones. They are located deep in the periventricular region and are particularly vulnerable to hypoxic ischemic injury. Similar to the arterial supply of the germinal matrix, the vessels branch primarily from the middle cerebral artery with minor contribution from the anterior and posterior cerebral artery. Active periventricular vascular growth and development occur between 24 weeks and 34 weeks of gestational age. Thus, preterm neonates are at risk for injury due to the immaturity in vasculature. As in the development of IVH, the lack of cerebral blood flow autoregulation producing a *pressure passive state* plays a key role in WMI. Using NIRS, studies have demonstrated the association of longer pressure passive states with a higher incidence of WMI. Microglia are abundant in cerebral white matter and particularly susceptible to ischemia. During the reperfusion phase, they produce free radicals and cytokines that lead to further injury. Maturing oligodendrocytes are sensitive to injury from free radicals leading to cell death. Inflammation due to maternal intrauterine infection or postnatal sepsis is

also a pathogenic mechanism that can coexist with ischemia (**Table 1**). Recent insight using serial MRI scans in premature infants has revealed that WMI is associated with altered brain development anatomically in regional brain volumes involving white matter, deep nuclear gray matter, cortex and surface folding measures and in functional connectivity measures compared to term born gestational age matched controls.

## RISK FACTORS

There are multiple risk factors for developing IVH in the preterm and term infant (**Table 2**). In the prenatal period, the most important is prematurity. The lower the gestational age and birthweight, the higher incidence of IVH. If preterm delivery is unavoidable, the route and location of delivery may have an impact. Previous studies have shown that preterm neonates delivered vaginally or those who endured labor for longer than 12 hours prior to delivery have a higher incidence of IVH. In addition, preterm neonates delivered by C-section who endured labor were more likely to develop IVH. Follow-up studies have contradicted previous results showcasing no difference in the route of delivery and development of IVH in the preterm population. Tertiary care centers are normally situated in major cities making it difficult for many pregnant women to have access to specialized care. Studies have shown that delivery at a level I or II center increases the incidence of IVH compared to matched gestational age neonates born at a tertiary care center.

Once a preterm neonate is in the NICU, the primary factor is the inability to autoregulate cerebral blood flow producing a pressure passive state. A neonate with respiratory distress syndrome (RDS) requiring mechanical ventilation could have fluctuating cerebral blood flow due to the mechanics of the ventilator and fluctuations in CO<sub>2</sub> levels, which are a potent regulator of cerebral vascular tone. A study comparing permissive hypercapnia levels (PaCO<sub>2</sub> between 45 mm Hg and 55 mm Hg) compared to the control group (PaCO<sub>2</sub> between 35 mm Hg and 45 mm Hg) showed no statistical significant difference in IVH. However, in another large study, hypercarbia (PaCO<sub>2</sub> > 60 mm Hg) positively correlated with IVH in preterm infants.

Hypotension in the early neonatal period can lead to ischemia of the germinal matrix and watershed areas in the brain. Hypotension requiring inotropic support increases the risk of developing IVH even more so. Factors that lead to increased cerebral blood flow such as tracheal suctioning, rapid infusion of colloid, seizures, and pneumothorax are associated with a greater risk of developing IVH. The neonatal hematocrit is inversely related to cerebral blood flow. As an adaptive mechanism, cerebral blood flow increases to maintain cerebral oxygen delivery in an anemic neonate. Without the ability to autoregulate cerebral blood flow, increased flow to the germinal matrix can lead to IVH.

## CLINICAL FEATURES (TABLE 3)

The majority of IVH is *clinically silent* and seen 25–50% of the time. It is often detected on a screening head ultrasound on the first or second day of life. Possible clues may be a failure of the hematocrit to rise after a packed red blood cell transfusion. The second most common presentation is *saltatory* or *stepwise*. There is a mild and fluctuating encephalopathy that is difficult to appreciate. Signs will gradually appear over days consisting of increased ventilator settings, mild acidosis on a blood gas, or hyperglycemia. The least common but acute presentation is *catastrophic*. The neonate may have bradycardia, hypotension, temperature fluctuations, pallor and poor perfusion, a tense bulging fontanel or severe hypotonia. These signs develop rapidly, within minutes to hours. Neonates become apneic, requiring increased respiratory support and intubation. Eventually, seizure activity and decerebrate posturing may occur. The medical team should be prepared for urgent resuscitation and treatment.

In term infants, clinical presentation can range from the first few days of life to a month of life. If there was a significant perinatal event leading to an IVH, signs usually present early in the course. Whereas if no inciting event occurred, infants remain stable until 2–4 weeks of life. The clinical presentation is usually more severe than seen in a preterm infant. Irritability, fever, apnea, and signs of intracranial pressure consisting of a bulging fontanel and vomiting

may appear. Seizures are particularly common, presenting in 50–65% of cases.

Clinical features of WMI are primarily developmental and seen after the neonatal period when delayed milestones are detected. Spastic diplegia is commonly seen with cystic WMI whereas cognitive effects seen without motor deficits present in neonates with non-cystic WMI. When there is associated neuronal or axonal injury, a wide spectrum of clinical deficiencies can develop from impairment in intelligence to falling on the spectrum of autistic disorders. Prior to discharge, increased appendicular tone, hyperreflexia, and ankle clonus consistent with upper motor neuron injury may be seen.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis is broad since the presenting signs and symptoms are not specific to IVH. Episodes of apnea and desaturation could point toward apnea of prematurity, gastroesophageal reflux, sepsis, necrotizing enterocolitis, or a central nervous system disorder. A sudden decrease in hematocrit could be the result of blood loss in the GI tract or necrotizing enterocolitis with perforation. Electrolyte abnormalities such as hyperglycemia and metabolic acidosis could be secondary to sepsis or necrotizing enterocolitis. Retractions, increased work of breathing and tachypnea could be RDS, sepsis or necrotizing enterocolitis. Physical exam findings of poor perfusion, lethargy or pallor could indicate sepsis.

## DIAGNOSIS

Intraventricular hemorrhage is diagnosed primarily using imaging modalities. The goal is to detect IVH in high-risk infants and for surveillance of future complications. CUS is the mode of choice due to its accessibility in NICUs worldwide. It is a low-cost noninvasive bedside test that is easy to perform in a busy intensive care unit and produces high-resolution images without ionizing radiation. Using the open anterior fontanel, one is able to visualize the ventricles and surrounding parenchyma. Papile and colleagues in 1979 developed a classification system of IVH based on head CT scans stratifying findings into four grades. Grade I is defined as a germinal matrix hemorrhage, where the bleeding is restricted to the subependymal zone of the ventricle (**Fig. 4**). Grade II is a hemorrhage that breaks through the germinal matrix and begins to fill the ventricular space (**Fig. 5**). Grade III is an IVH that expands causing ventricular dilatation (**Fig. 6**). In a Grade IV hemorrhage, a triangular fan shaped echodensity is seen in the peritrigonal parenchyma (**Fig. 7**).

More recently, an updated classification system developed by Volpe takes into account the percentage of ventricle filling by the bleed. A Grade II is diagnosed when the bleed fills 10–50% of the ventricle, Grade III if it is greater than 50% of the ventricle and Grade IV if there is an intraparenchymal echogenicity now known as a PVHI.

Based on multiple studies documenting the timing of an IVH, routine screening with a head ultrasound is recommended on day 1–3 of life, 7–14 of life and then at 36–40 weeks of PMA for neonates born less than 30 weeks of gestation or less than 1,500 g (VLBW). Follow-up ultrasounds are obtained to monitor for extension of the bleed and development of common complications such as PHVD.

Detection of lower grade hemorrhages can be difficult using ultrasound. Inter-rater reliability of head ultrasound interpretation is very good with Grades III and IV IVH; however, it decreases significantly with Grades I and II IVH and WMI. In WMI, CUS will show bilateral linear echodensities near the lateral ventricles. However, ultrasound is unreliable for detecting small focal necrosis and myelin loss that can be visualized with MRI.

**Figure 4** Sagittal view of a Grade I IVH

**Figure 5** Coronal view of a bilateral Grade II IVH

**Figure 6** Coronal view of bilateral Grade III IVH

## MRI Studies

In tertiary NICUs in the USA, many MRI studies are completed at term equivalent age in VLBW infants to better assess brain development and delineate injury. Compared to ultrasound, MRI is

better at depicting anatomical landmarks in the brain. In addition, it has greater sensitivity and specificity in diagnosing WMI and parenchymal pathology. PVHI can be diagnosed by ultrasound; however, MRI is more accurate in determining size and exact location of the bleed. In term infants at risk of having a sinovenous thrombosis, MRI is the best modality for diagnosis. Using specific regions of the brain, such as the posterior limb of the internal capsule, term equivalent MRIs can aid in predicting future motor dysfunction. Due to advances in child life procedures, neonates tolerate MRI scans without sedation relatively well using devices like the MedVac<sup>®</sup> bag (CFI Solutions, Fenton, MI, USA). With the advent of MRI compatible ventilators and monitoring equipment, the ability to obtain an MRI in a critical neonate is easier. There are several qualitative and quantitative tools available to score neonatal brain MRI scans. However, specialized neuroradiological input is required for appropriate interpretation of neonatal MRIs.

## MANAGEMENT

As is the case of many diseases in medicine, the primary goal in management is to prevent the problem and provide supportive care. Monitoring electrolyte levels, respiratory mechanics and hemodynamic status are a few measures to play close attention to. Maximizing intravenous and/or enteral nutritional support is important for growth and healing. Weekly head circumference surveillance is helpful in monitoring for complications such as PHVD. With large IVHs, early detection and treatment of seizure activity with antiepileptics may improve long-term outcome. In the catastrophic presentation, resuscitation including intubation, volume expansion, and inotropic medication for abrupt hemodynamic change, and chest compressions may be needed to stabilize the critically ill neonate.

## COMPLICATIONS

The most frequent complication of IVH is PHVD. PHVD evolves over 1–3 weeks and is most often associated with higher Grade IVH. Risk of progression to ventricular dilatation is 5% in Grade I IVH and 20% in Grade II IVH. PHVD can occur rapidly in situations where the blood clot obstructs the foramen of Monro (obstructive PHVD) but more commonly intraventricular blood results in decreased reabsorption of CSF at the arachnoid villi due to an obliterative arachnoiditis in the basal cisterns mediated by upregulated fibroblasts and deposition of extracellular matrix proteins within the subarachnoid villi.

Clinical features, such as a bulging fontanel, diastasis of the sutures and increase in head size, *do not present for weeks after ventricular dilatation* due to the higher water content and compressibility of the preterm brain and the large subarachnoid space. Thus, serial head ultrasounds (**Fig. 8**) are recommended to monitor for development of PVHD. In half of the patients, PVHD is transient and will resolve on its own. Depending on the severity of the PHVD and clinical condition of the neonate, the two options in management are reservoir or ventriculoperitoneal shunt (VP shunt) placement. Reservoirs are often first line therapy whereas a VP shunt is considered if no improvement is seen with reservoir taps by term equivalent age (**Flow chart 1**). It is estimated that neonates with Grade III IVH will require a VP shunt 18% of the time and up to 29% in Grade IV IVH (PVHI). Similar to the high risk of PHVD in preterm Grade IV IVH, 50% of term infants with large bleeds will require a VP shunt.

Intraparenchymal blood can irritate the surrounding cortical tissue leading to seizure activity. The majority of seizures in preterm neonates are subclinical. Continuous EEG for at least a 24 hours period in high-risk neonates is warranted to monitor for any abnormal electrical activity. Early diagnosis and treatment of seizure activity in the neonate may impact long-term neurodevelopmental outcome. PVHI is a unilateral venous infarction that forms a single large porencephalic cyst that rarely disappears over time (**Fig. 9**). Porencephalic cysts are the most common sequela of a PVHI forming over a period of 1–8 weeks. The incidence is as high as 66% in patients with a PVHI. It is often difficult to distinguish a PVHI from WMI. Destruction of developing oligodendrocytes leading to impairment of myelination affects the long-term outcome. WMI is most often an arterial disturbance that is symmetrical in nature with more diffuse cerebral WMI compared to PVHI, which is predominantly a unilateral lesion in as many as 80% of infants. WMI develops over days to weeks after delivery whereas PVHI forms much earlier in the course of injury. It progresses into multicystic injury that becomes less apparent over time.

## OUTCOME

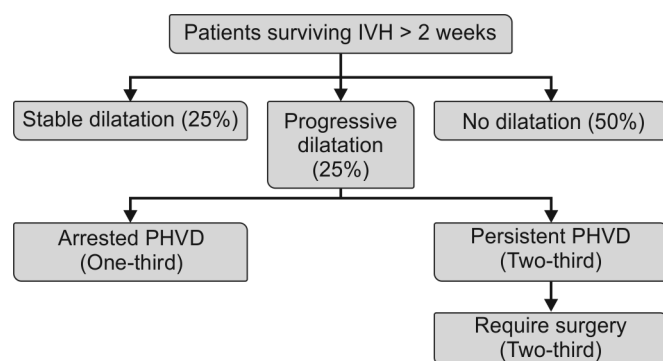

As more preterm neonates are surviving the NICU, the morbidity and mortality due to IVH remain at a steady state. In preterm neonates, Grades I and II IVHs generally resolve without significant complications. However, recent data out of Australia revealed that presence of Grades I and II IVH can be associated

**Figure 7** Coronal view of a Right Grade IV IVH

**Figure 8** Coronal Ultrasound demonstrating posthemorrhagic ventricular dilatation

**Flow chart 1** Natural course of IVH and PHVD

with poor neurodevelopmental outcome. In their cohort, preterm infants with IVH had significantly lower mental developmental (MDI) scores compared to matched infants with normal head ultrasounds. In addition, higher rates of cerebral palsy were seen in the IVH group. Neurological sequelae are seen in 35% of preterm infants with a Grade III IVH and as high as 90% in neonates with PVHI. Mortality rates increase significantly to 20% in Grade III and 50% in Grade IV. The major outcome in PVHI is motor dysfunction, specifically spastic diplegia. The spastic diplegia occurs more often in the lower extremity. In neonates with PHVD requiring VP shunt placement, Bayley Scales of Infant and Toddler Development at 2 years are significantly lower compared to PMA matched neonates without shunt placement. Term infants more often develop a higher Grade IVH (Grade III or IV). Thus, they are prone to develop neurodevelopmental complications associated with moderate to severe IVH. In published data, IVH in term infants with thalamic involvement seem to have a worse prognosis with higher risk of developing cerebral palsy.

Similar to PVHI, long-term neurological dysfunction commonly seen with WMI is spastic motor paresis and cognitive deficits. The corticospinal tracts pass through the periventricular region with the lower extremity bundles most adjacent to the lateral ventricles. Moderate to severe white matter abnormalities seen on MRI showed a statistically significant association with neurodevelopment outcomes. Specifically, cognitive and psychomotor delay, cerebral palsy and neurosensory impairment are common. Deep gray matter injury seen on MRI also correlated with cognitive delay and motor impairment.

## PREVENTION (TABLE 4)

Intraventricular hemorrhage prevention in the preterm infant is a tough goal to accomplish. The best way to prevent IVH is delaying preterm birth as long as possible. If preterm delivery is inevitable, administration of maternal corticosteroids reduces the risk of developing an IVH. Steroids are well documented to accelerate the maturity of the brain, improving the pressure passive state. In vitro studies have shown steroids up-regulate GFAP in pericytes improving vascular stability. Lung maturity is improved and the need for inotropic support is reduced. A few studies have shown that antenatal administration of magnesium sulfate may protect against IVH. The exact mechanism of the protective effect of magnesium sulfate is unknown. There is some evidence that magnesium sulfate is able to neutralize reactive oxygen species and enhances the preterm antioxidant system.

**Figure 9** T2 weighted MRI scan demonstrating a right-sided resolving PVHI (arrow), which has evolved into a porencephalic cyst that has merged with the lateral ventricle

**Table 4** Potential interventions to reduce brain injury (IVH and white matter injury) in preterm infants

Prevention of white matter injury	
Antenatal	<ul style="list-style-type: none"> <li>• Antenatal steroid use</li> <li>• Magnesium sulfate in preterm labor</li> <li>• Transportation in utero</li> </ul>
Delivery	<ul style="list-style-type: none"> <li>• Route of delivery</li> <li>• Delayed cord clamping</li> </ul>
Resuscitation	<ul style="list-style-type: none"> <li>• Temperature regulation</li> <li>• Optimize ventilation</li> </ul>
NICU	<ul style="list-style-type: none"> <li>• Head in midline and raised for 72 hours</li> <li>• Early extubation</li> <li>• Maintain target temperature</li> <li>• Maintain target PCO<sub>2</sub> levels</li> <li>• Avoid/manage blood pressure fluctuations</li> <li>• Indomethacin prophylaxis</li> <li>• Nutrition (early TPN, breastmilk)</li> <li>• Avoid postnatal steroids</li> </ul>

Once the preterm neonate is delivered, delayed cord clamping (30–90 seconds) has shown encouraging outcomes in recent studies. Higher blood pressure, better cerebral oxygenation and lesser days on the ventilator are seen in the delayed cord-clamping group with a significant reduction in IVH rates. The use of Indomethacin prophylaxis has shown promising results with a recent meta-analysis of 19 trials showing a decrease in the incidence of severe IVH (Grade III or IV). Specifically, the greatest reduction occurred in male preterm neonates less than 25 weeks of gestational age. Animal studies and postmortem autopsies of preterm infants have shown indomethacin increases key components of the basal lamina improving structural integrity of the germinal matrix vasculature. Muscle paralysis and sedation has been shown to improve the fluctuation in cerebral blood flow in preterm neonates requiring mechanical ventilation. However, there are risks that go hand in hand that need to be considered when deciding to use paralytics and sedation in this population.

### IN A NUTSHELL

1. IVH, cerebellar hemorrhage and white matter injury (WMI) are the predominant forms of brain injury seen in VLBW infants and often coexist.
2. IVH originates in the germinal matrix. The severity of IVH is Graded (I–III) depending on location and amount of blood resulting from ischemia-reperfusion injury coupled with a pressure passive cerebral blood flow. Grade IV or periventricular hemorrhagic infarction (PVHI) results from venous infarction in the peritrigonal area due to obstruction of venous drainage.
3. White matter injury can be focal or diffuse and microscopic (more common) or macroscopic (cystic). It is the predominant injury of the preterm infant.
4. IVH can be clinically silent and only detected on screening cranial ultrasound (CUS). A mastoid view of the cerebellum should be included in the standard CUS protocol. WMI and smaller cerebellar bleeds may also be clinically silent and best detected on a term equivalent MRI.
5. White matter injury involves injury to the preoligodendroglial cell (OL-1 stage) whose expression peaks between 24 weeks and 34 weeks PMA. The injury is mediated by inflammatory, excitotoxic and oxidative mechanisms and results in not only a reduction in absolute OL-1 cells but a maturational arrest of these cells.
6. IVH, depending on severity, results in destruction of the germinal matrix and posthemorrhagic ventricular dilatation (PHVD) that may require a temporizing surgical measure (reservoir) and some of these infants may require a ventriculoperitoneal shunt.
7. Anatomic characteristics of the VLBW infant brain result in PHVD occurring with minimal increase in the occipitofrontal circumference (OFC). Thus CUS screening twice a week is essential to detect ventricular dilatation that can happen rapidly with CSF flow obstruction.
8. Clinical bundles can be created to prevent IVH and reduce WMI in VLBW infants.
9. Neurodevelopmental outcomes worsen across domains with severity of IVH, especially with the need for VP shunt placement following PHVD.
10. Presence of moderate to severe white matter abnormalities on MRI at term equivalent age is associated with significant developmental delay across cognitive, motor and language domains in later childhood.

Avoiding hypothermia, hypercarbia/hypocarbia and maintaining hemodynamic stability is critical in the first week of life. Keeping the head midline with the infant supine and the head end raised by 15 degrees and avoiding volume expanders and inotropes when possible have been shown to decrease the incidence of IVH when used as a *bundle* of practice.

In order to prevent WMI, prompt recognition of impaired cerebral blood flow is essential. As stated earlier, the use of NIRS monitoring can aid in diagnosis of a pressure passive state in real time. Preventing the impaired cerebral blood flow through supportive measures described for IVH are important in WMI as well. Finally, ongoing research on the use of free radical scavengers in preventing oligodendrocyte injury could potentially improve neurodevelopmental outcomes in preterm neonates at risk.

# Section 17 RESPIRATORY PROBLEMS OF THE NEWBORN INFANT

Section Editor Siddarth Ramji

## Chapter 17.1

### Approach to a Neonate with Respiratory Distress

Swarna Rekha Bhat

Respiratory distress of any etiology accounts for a significant proportion of morbidity and mortality in the neonatal period. The etiology may be diverse but the basic supportive measures include oxygen and ventilator support when distress is severe. It is, therefore, important to be able to assess severity of respiratory distress to decide the treatment modality. It is equally important to be able to determine the etiology as treatment varies from simple supportive measures to surgery if the cause of distress is surgical. This section will deal with clinical approach to respiratory distress in neonates to help determine etiology and assess severity.

#### EPIDEMIOLOGY

As per the neonatal perinatal database 2002–2003, incidence of respiratory problems among intramural neonates was 5.7% of all livebirths. Among these, transient tachypnea of newborn (TTNB) accounted for 55.7% of respiratory distress, followed by meconium aspiration syndrome (MAS) accounting for 22.5% and respiratory distress syndrome (RDS) accounting for 19.9% of respiratory morbidity. Respiratory problems, particularly RDS, accounted for nearly 16% of neonatal mortality. Data from Kumar et al. suggested a similar pattern; overall incidence of respiratory problems was 6.7% of livebirths and TTNB was the most common cause (42%), followed by pneumonia (17%), MAS (10%) and RDS (9%). The same data also suggests that among surgical causes, the most common cause of respiratory morbidity was esophageal atresia with or without tracheoesophageal fistula (TEF).

#### ETIOLOGY

It is important to understand that causes of respiratory distress in neonates need not necessarily be respiratory problems, though this is the commonest cause. Breathing difficulty can occur because of respiratory, cardiac, metabolic, CNS and surgical causes. The common causes of respiratory distress are enumerated in **Table 1**. These include respiratory distress syndrome, meconium aspiration syndrome, pneumonia, pneumothorax and persistent pulmonary hypertension of newborn. This table also highlights the time of onset of respiratory distress in each of these conditions.

**Table 2** lists some of the less common causes of respiratory distress. One should think of these if usual causes are ruled out. Particularly, conditions such as primary surfactant deficiency, primary ciliary dyskinesia are rare causes. It is important to identify surgical causes as early as possible so that corrective action can be taken as soon as possible.

**Table 3** summarizes the cardiac conditions that can cause respiratory distress in neonates. One must suspect cardiac cause, if there are malformations, cyanosis, hepatomegaly or shock. Identifying these conditions is important as duct-dependent lesions will need immediate treatment with prostaglandins.

#### CLINICAL APPROACH

A neonate may present at birth or at any time subsequently in the first 28 days of life with respiratory distress. Priority is to assess the severity and decide regarding need for immediate intervention. This should be followed by a detailed history and examination to determine etiology.

**Table 1** Common causes and time of onset of respiratory distress in newborns

Condition	Predisposing factor	Onset
Respiratory distress syndrome (RDS)	More common in preterm	< 6 hours
Chronic lung disease	Preterms on ventilator	> 1 week
Transient tachypnea of newborn (TTNB)	Occurs mostly in term neonates, but can occur in preterms	< 6 hours
Meconium aspiration syndrome (MAS)	Occurs in term SGA and post-term neonates	< 6 hours
Pneumonia	Can occur in term and preterm	Any time
Pneumothorax	MAS, ventilated neonate	Any time
PPHN	Setting of MAS or asphyxia	< 6 hours
Malformations		< 6 hours
Pulmonary hypoplasia	Oligohydramnios, congenital diaphragmatic hernia	< 6 hours
Pulmonary hemorrhage	Pneumonia, sepsis, cardiac problem	Any time
Asphyxia		Any time
IEM		After 5 days
Cardiac		> 6 hours
Metabolic acidosis	Dehydration, IEM	Any time
Pleural effusion	Unusual, often can be chylous or associated with hydrops	

**Table 2** Less common causes of respiratory distress in the newborn

Small chest syndromes	Asphyxiating thoracic dystrophy Achondroplasia Osteogenesis imperfecta Thanotrophic dysplasia Campomelic dysplasia Hypophosphatasia
-----------------------	--

Contd...

Contd...

Malformations	CCAM Congenital lobar emphysema Lung cyst Pulmonary sequestration Congenital pulmonary lymphangiectasia Pulmonary alveolar proteinosis Primary ciliary dyskinesia Primary surfactant deficiency
Airway abnormality	Choanal atresia Midfacial hypoplasia Macroglossia Micrognathia Laryngeal web Tracheal stenosis Subglottic stenosis Laryngotracheomalacia
Neuromuscular diseases	SMA Myopathy
Aspiration syndromes (causes of aspiration)	<i>Sucking-swallowing incoordination:</i> GERD Neuromuscular diseases HIE Preterm Cleft palate Pierre Robin sequence TEF Laryngeal cleft

**Abbreviations:** CCAM, congenital cystic adenomatoid malformation; SMA, spinal muscular atrophy; GERD, gastroesophageal reflux disease; HIE, hypoxic-ischemic encephalopathy; TEF, tracheoesophageal fistula.

**Table 3** Cardiac causes of respiratory distress in neonates

	Condition	Time of onset
Structural heart disease	Hypoplastic left heart, interrupted aortic arch, coarctation of aorta, aortic stenosis	First week
	Truncus arteriosus, TGA, TAPVC, DOV	2–3 weeks
	VSD, AP window	After 3 weeks
AV malformations		Any time
Arrhythmias		
Myocarditis/myocardial dysfunction	Hypoxic ischemic encephalopathy, infections	
Cardiomyopathy	Other malformations, inborn errors of metabolism	

**Abbreviations:** TGA, transposition of great arteries; TAPVC, total anomalous pulmonary venous circulation; DOV, double outlet ventricle; VSD, ventricular septal defect; AP, aortopulmonary.

**Table 4** Silverman Anderson score for respiratory distress in preterm neonates

	Upper chest	Lower chest	Xiphoid retraction	Dilatation of nares	Expiratory grunt
Score 0	Synchronized respiration	None	None	None	None
Score 1	Lag on inspiration	Just visible	Just visible	Minimal	Heard with stethoscope
Score 2	See-saw movements	Marked	Marked	Marked	Heard with naked ear

Score 10 = Severe respiratory distress; Score  $\geq 7$  = Impending respiratory failure; Score 0 = No respiratory distress

## Assessing Severity of Respiratory Distress

Respiratory rate by itself will not determine the severity of respiratory distress: sometimes when there is severe distress, respiratory rates may be lower and the neonate can even become apneic. The two scoring systems usually used in the neonatal period are the Silverman Anderson score, usually used for preterm neonates and the Downe's score usually used for term neonates. The Silverman score is based predominantly on retractions and therefore may over- or underscore depending on the underlying condition (**Table 4**). The Downe's score is more comprehensive and includes need for oxygen and can be used for all neonates (**Table 5**).

If the distress is mild, monitoring is sufficient. Moderate distress would need blood gas estimation to determine degree of hypoxia and hypercarbia, and severe distress would require immediate intubation and ventilation. Neonates with moderate distress may be managed on invasive or noninvasive ventilation. Neonates with mild distress may require oxygen or noninvasive respiratory support, particularly in preterm neonates.

## Determining the Etiology

### History

If distress has occurred immediately after birth or within the first few hours of birth, details of antenatal, natal and immediate postnatal events are important. Important points to be asked in antenatal, natal and postnatal history are summarized in **Box 1**.

### Examination

**Severity of distress** As mentioned earlier, the priority is to assess severity of respiratory distress. For this, one needs to look for respiratory rate, suprasternal, intercostal, subcostal retractions, flaring of alae nasi and grunting, cyanosis, irritability or drowsiness. Increased respiratory rate not associated with distress or retractions is usually termed as tachypnea. The most likely cause of tachypnea without retractions is transient tachypnea of newborn. Milder degrees of respiratory distress will also have no retractions. Suprasternal retractions usually indicate an upper airway problem. Cyanosis, irritability or drowsiness suggest that there is some amount of hypoxia.

**General examination** Importance of checking if the baby is pre- or post-term, small for gestational age (SGA) or large for gestational

**Table 5** Downe's respiratory distress scoring system for term neonates

Score	0	1	2
RR/min	<60	60–80	>80
Cyanosis	none	in room air	In >40% oxygen
Retractions	none	mild	Moderate to severe
Grunting	none	Audible with stethoscope	Audible without stethoscope
Air entry	normal	decreased	Barely audible

Mild: 0–3; Moderate: 4–6; Severe: 7 and more

**BOX 1 Taking history in a neonate with respiratory distress***Antenatal history*

- History of decreased fetal movements may suggest neuromuscular disease
- History of oligohydramnios could indicate possibility of pulmonary hypoplasia, history of polyhydramnios could suggest TEF or maternal diabetes
- History suggestive of intrauterine infections may point towards a congenital pneumonia
- Attempt should be made to find out if an anomaly scan has been done to identify any cardiac or respiratory malformations
- Maternal diabetes may help identify polycythemia or TTNB as a cause of respiratory distress
- Maternal fever and evidence of chorioamnionitis should be asked for to see if early onset sepsis and pneumonia is causing the problem.

*Natal history*

- Prolonged rupture of membranes could lead to early onset sepsis and pneumonia
- Prolonged duration of labor, difficult delivery could suggest asphyxia as an etiology
- Meconium stained liquor would indicate MAS, asphyxia, PPHN
- Caesarian delivery is likely to be associated with TTNB
- Requirement of resuscitation would indicate: asphyxia, acidosis, pneumothorax as cause of distress.

*Postnatal history*

- *Weight and gestation:*
  - Preterm neonates are most likely to have RDS
  - Post-term neonates and term SGA neonates are more likely to have MAS
  - LGA neonates are likely to have TTNB and hypoglycemia as an etiology for tachypnea
- *Onset of respiratory distress:* This probably gives one of the most important clues for cause of respiratory distress.
  - Onset of respiratory distress immediately after birth or within first few hours is likely to suggest respiratory distress syndrome, Meconium aspiration syndrome, transient tachypnea of newborn, birth asphyxia, congenital malformations. Less frequent causes of respiratory distress occurring in the first few hours would be persistent pulmonary hypertension and pulmonary hypoplasia
  - Transient early causes of tachypnea would include delayed clearance of lung fluid, metabolic acidosis, hypothermia, hypoglycemia and polycythemia
  - Most other causes of respiratory distress occur after 6 hours of life.
- History of facial dysmorphism would indicate aspiration or upper airway cause of distress
- Frothing or persistent regurgitation can point to esophageal atresia and trachea esophageal atresia as an etiology
- Cyanosis would suggest cyanotic heart disease or PPHN
- A normal neonate deteriorating on day 5–7 would indicate possibility of inborn error of metabolism
- A normal neonate deteriorating towards end of first week could also indicate cardiac problems
- History of lethargy, poor feeding followed by respiratory distress would suggest aspiration as a cause of respiratory distress
- History of lethargy, poor feeding, grunting and cyanosis would also indicate severe distress
- History of prolonged ventilation would mean either a ventilator-associated pneumonia or chronic lung disease, particularly in a pre-term neonate.

*Abbreviations:* TEF, tracheoesophageal fistula; TTNB, transient tachypnea of newborn; MAS, meconium aspiration syndrome; PPHN, persistent pulmonary hypertension of the newborn; RDS, respiratory distress syndrome; SGA, small for gestational age; LGA, large for gestational age.

cleft palate and distress could be having aspiration pneumonia, or a neonate with features of Down's syndrome could be having a cardiac problem. Similarly, if there is micrognathia, the distress could be due to an upper airway problem or a neck mass could also be causing an upper airway obstruction. Potter facies will help identify pulmonary hypoplasia as cause of respiratory distress. A neonate who has failure to thrive or dehydration and has tachypnea is most likely to be having metabolic acidosis.

**Respiratory system examination** In respiratory system, one must look at the shape of the chest. A hyperinflated chest is most likely to occur in MAS or a congenital diaphragmatic hernia. A neonate with congenital diaphragmatic hernia in addition will have a scaphoid abdomen. If the chest is small, it could be any of the small chest syndromes. The type of sounds associated with respiratory distress is also useful; nose block, grunt or stridor, all give clues to the diagnosis.

Cyanosis is most likely to occur in a neonate with severe distress, cyanotic heart disease and PPHN. Cyanosis improving with crying has been typically described in bilateral choanal atresia. Decreased air entry bilaterally would suggest a condition like severe RDS, and unilateral decreased air entry is most likely to be due to pneumothorax, collapse or congenital lobar emphysema. It is important to check for position of heart sound as it might have shifted to the right side in diaphragmatic hernia or left-sided pneumothorax. Crepitations may be heard in pneumonia.

**Other systems** In a neonate with respiratory distress, cardiovascular examination should be done to look for murmurs, tachycardia and cardiomegaly. One must look for hepatomegaly to identify cardiac failure. A CNS examination is necessary to see if cause of tachypnea is central neurogenic hyperventilation. A neonate who has Erb palsy and distress may be due to phrenic nerve palsy. Severe hypotonia in a neonate with respiratory distress would indicate that respiratory distress could be due to neuromuscular disease.

**Pulse oximetry** Currently pulse oximetry should be considered as part of clinical examination of a neonate with respiratory distress. It is always useful to check the preductal saturation. If both preductal and postductal saturations are checked, a difference would suggest right to left shunting.

**Arterial blood gases** Blood gases should be determined for any neonate with moderate or severe respiratory distress. Blood gas assessment helps in determining etiology, severity of illness and the need for respiratory support.

**Chest X-ray** Chest skiagram is mandatory in any neonate with respiratory distress. It helps identify etiology and helps to rule in or rule out any malformations. Any chest X-ray taken in a neonate should be with a nasogastric tube *in situ*, so that by this simple test TEF or esophageal atresia can be identified.

### Causes of Transient Respiratory Distress

Conditions such as delayed lung fluid clearance, hypothermia, mild metabolic acidosis, hypoglycemia, polycythemia, amniotic fluid aspiration can cause transient respiratory distress, which disappears after correcting the underlying problem.

### Causes of Persistent Respiratory Distress

If a preterm neonate continues to require ventilatory support, one must consider chronic lung disease, ventilator-associated pneumonia or presence of a patent ductus arteriosus. In a term neonate requiring continued support, one must consider PPHN, ventilator-associated pneumonia. Cardiac disease, structural malformations, inborn errors of metabolism and rare causes of respiratory distress like primary surfactant deficiency may cause persistent distress and require continued respiratory support.

age (LGA) has already been mentioned in the history section. The next most important step in general examination would be to look for dysmorphic features and malformations. A neonate with

### Distinguishing PPHN from Cyanotic Heart Disease

Many times a neonate presents with significant respiratory distress and cyanosis. In the absence of an echocardiography, it is difficult to rule in or rule out a cardiac condition. A hyperoxia and hyperventilation test will help in distinguishing PPHN from cyanotic heart disease. In cyanotic heart disease the  $\text{PaO}_2$  will be between 100 and 150 mm Hg and usually will not exceed 100 mm Hg with the test, whereas in PPHN the  $\text{PaO}_2$  will increase beyond 100 mm Hg when hyperoxia and hyperventilation are provided. A greater than 10% difference in the pre- and postductal oxygen saturation is also useful to determine the presence of a right to left shunt.

### IN A NUTSHELL

1. It is important to assess severity of respiratory distress in the newborn by using a respiratory distress score
2. Etiology can be respiratory or nonrespiratory
3. Common causes include RDS in preterm neonates and MAS and pneumonia in term neonates
4. Surgical causes must be ruled out as these are correctible by surgical intervention
5. History, particularly age of onset of respiratory distress, is useful to determine etiology
6. Pulse oximetry should be considered to be part of clinical examination in a neonate with respiratory distress
7. Chest skiagram is useful in determining the etiology of respiratory distress in the neonate and should always be taken with a nasogastric tube in situ.

## Chapter 17.2

# Neonatal Apnea

Manoj Modi

Apnea is a disorder of respiratory control characterized by an abnormal pause during spontaneous breathing. Though exact mechanisms for occurrence of apnea and associated risk factors are not completely elucidated till date, advent of molecular genetics has led to great improvement in our understanding about nature of this dreaded condition. Most common diagnosis for apnea in neonates is apnea of prematurity (AOP), which is believed to be an effect of immaturity of respiratory control.

## FETAL BREATHING AND TRANSITION AT BIRTH

During fetal life, breathing is intermittent and occurs during the low-voltage electrocortical state. Immediately after birth, as a part of extrauterine adaptation, breathing becomes continuous, irrespective of electrocortical state. The regulatory mechanisms for this transition from intrauterine life are not precisely elucidated. The continuous breathing after birth may be a result of altered threshold of peripheral and central chemoreceptors, which now trigger at lower PCO<sub>2</sub> and higher PO<sub>2</sub> of neonates. In addition, it is believed that somatic sensory stimuli after birth lead to suppression of midbrain inhibitor by increasing neuronal traffic in brainstem.

Though breathing is continuous in most term neonates, brief pauses of 5–10s, after 15–20s of regular breathing are not uncommon. This pattern of breathing is called periodic breathing. Periodic pattern of breathing is related to gestational age and has been observed for up to 25% of the breathing time in preterm neonates compared to 2–5% of time in term neonates. The occurrence of periodic breathing declines substantially by 40–50 weeks postconceptional age. This pattern of breathing is observed more often during REM sleep, though it may also occur during awake state or quite sleep. However, this breathing pattern is inconsequential, as it is not associated with any change in heart rate or oxygen saturation. These neonates require no treatment and their later outcome is excellent. AOP is considered as an extension of periodic breathing, though some researchers doubt this association.

## DEFINITION AND CLASSIFICATION

Apnea is defined as prolonged cessation of air flow, which may be associated with change in oxygen saturation and heart rate. However, there is no consensus regarding duration of respiratory pause, or degree of change in saturation and heart rate, which should be considered abnormal. The most widely used definition of AOP is cessation of respiration in preterm neonates, which lasts for more than 20s, or is accompanied by fall in oxygen saturation to less than or equal to 80% or fall in heart rate to less than two-third of baseline lasting for greater than or equal to 4s.

Traditionally, apnea in neonates is classified into three categories: central, obstructive and mixed. *Central apnea* is characterized by a complete cessation of respiratory efforts without an involvement of airway obstruction. *Obstructive apnea* is characterized by cessation of airway flow, where neonate tries to breathe against an obstructed upper airway. In *mixed apnea*, there is element of both central and obstructive apnea. Mixed apnea accounts for about 50% of all cases of apnea in premature neonates, followed by central apnea (40%) and obstructive apneas (10%).

## INCIDENCE

The incidence of AOP is inversely correlated with gestational age and birthweight. Approximately 50% of very low birthweight infants and almost 100% extremely low birthweight infants experience apnea during birth hospitalization. Incidence of AOP is 10–15% at 32–35 weeks gestation, approximately 50% at 30–31 weeks, and nearly 100% at gestation below 29 weeks. Apneas usually resolve by 40–44 weeks postmenstrual age (PMA) in most preterm neonates.

## PATHOGENESIS

The exact pathogenesis of AOP is poorly understood. It is believed to be due to functional immaturity of respiratory centers in brainstem that regulate breathing, mainly via central chemoreceptor zone. This is manifested in the form of an immature ventilatory response to hypercapnia and hypoxia and an exaggerated inhibitory response to mechanical or chemical stimulation of airway receptors. Ventilatory response of a preterm neonate is further modified by a number of other coexisting morbidity factors or disease states.

### Diminished Hypercapnic Response

Term neonates and adults respond to hypercapnea with an increase in their minute ventilation by increasing both tidal volume and respiratory rate. This ventilatory response to hypercapnea is mainly mediated through stimulation of chemosensitive zone on the ventrolateral surface of the medulla. In contrast to term neonates, hypercapnic exposure in preterm neonates is associated with prolonged expiratory duration. This altered response to hypercarbia, in preterm neonates, is attributed to structural and functional immaturity of medullary chemosensitive zone. Furthermore, in preterm infants, there is upregulation of multiple inhibitory neurotransmitter including  $\gamma$ -aminobutyric acid (GABA), adenosine, endorphins, and prostaglandins, which could be additionally implicated for this aberrant response.

### Hypoxic Depression

Preterm infants respond to a decrease in ambient oxygen with a transient increase in respiration, which is subsequently followed by a sustained respiratory depression. This biphasic response to hypoxia in preterm infants is postulated to be due to an initial stimulation of peripheral chemoreceptors, followed by an overriding depression of the central medullary receptors. It is unclear if this biphasic ventilator response to hypoxia is an initial triggering factor for development of apnea or not, hypoxia may aggravate apnea and result in delayed recovery of the infant.

### Enhanced Inhibitory Reflexes

Cessation of breathing in response to laryngeal stimulation is a protective reflex that prevents aspiration of contents in lungs. In preterm infants, there is an exaggerated response to stimulation of laryngeal mucosa, leading to prolonged apnea. The precise mechanisms for this maturational difference in laryngeal reflex-induced apnea are not known.

### Upper Airway Instability

An in-coordination between upper airway and chest wall muscle responses to chemoreceptor stimulation might be additional explanation for apnea of prematurity, particularly for mixed apnea. In mature neonates, upper airway muscle activity precedes the diaphragmatic contractility ensuring upper airway patency at peak inspiratory flow. It is believed that in preterm infants, activation of diaphragm precedes activation of upper airway, causing pharyngeal structures to collapse, leading to obstruction of upper airway during inspiratory efforts. This delayed activation of upper airway muscle may either trigger or prolong the apneic episode.

### Mechanoreceptors

The Hering-Breuer reflex is a reflex triggered to prevent overinflation of the lungs. This is mediated by stretch receptors present in the smooth muscle of the airways, which respond to excessive stretching of the lung during large inspirations by sending inhibitory signals to brainstem through vagus nerve. The strength of this reflex increases with gestation, consistent with a maturational increase of respiratory drive induced by the stretch receptors and may play a role in the reduced ventilatory drive seen in preterm infants.

### Sleep State and Apnea

Apnea of prematurity is observed more frequently during active sleep. This could be partly explained by paradoxical activity of intercostal muscles during respiration, due to spinal inhibition. This leads to inward movement of chest wall during inspiration, particularly in extremely preterm infants with a more compliant chest wall. This leads to a decrease in functional residual capacity (FRC) and impaired oxygenation, hence predisposing the preterm neonate to apnea.

### Gastroesophageal Reflux

Gastroesophageal reflux (GER) and apnea, both are common occurrence in preterm infants and both often coexist. GER is frequently attributed as cause of apneic episodes; however, role of GER in causation of apnea is debatable. Many studies have evaluated temporal relationship between apnea and GER. Findings of these studies suggest that even when apnea and GER coexist, apnea usually precede the reflux episode. Hypoxia associated with apneic episode is suggested to reduce tone of lower esophageal sphincter, predisposing to GER.

### Feeding-related Apnea

Preterm infants frequently experience apnea during feeding sessions, which are usually obstructive or mixed in nature. This could be related to immaturity of sucking-swallowing-respiration coordination. This results in onset of breathing efforts; while milk contents are still there in pharynx, leading to obstruction of airway during inspiration. In addition, there is a marked ventilatory depression during the initial continuous sucking phase of feeding. Activation of the laryngeal chemoreflex, repeated swallowing and prolonged airway obstruction may be attributed as possible factors for this ventilatory depression. This feeding-related apnea usually resolve by 44–54 weeks gestation. Infants with chronic lung disease and neurologic abnormalities have a higher propensity of feeding-related apneic episodes.

## MONITORING AND EVALUATION

As apnea are common in preterm neonates, particularly during first few days after birth, all preterm infants less than 35 weeks gestation should preferably be monitored for apneic spells for first week of life. There is a rapid decline in apneic episodes in most preterm infants after first few weeks. However, in very preterm infants, apnea may continue for 40–44 weeks postmenstrual age (PMA) warranting a continuous monitoring. All sick or unstable neonates, irrespective of their gestation should also be evaluated for apnea, till the time they become stable and alert.

Apnea may be detected by transthoracic impedance pneumography, which detects respiration by change in impedance over chest with movement of air. Electrodes are placed on either side of the chest above and below the diaphragm. With inhalation, air fills in the lungs, increasing the impedance across thoracic cavity. This is interpreted by the monitor as respiratory movement. If there is no movement of air in lungs, it is interpreted as apnea. A major limitation of impedance technology is that it cannot detect obstructive apnea. An alternative device to monitor apnea is nasal thermistor, which detects the presence of flow across nares by a

rise in temperature of thermistor, on contact with exhaled warm air. Many units do not have access of these devices and use routine pulse oximetry to diagnose apnea. An apneic episode associated with desaturation and/or bradycardia will generate an alarm, which will drag attention of caregiver. Many centers offer home apnea monitoring for neonates, who are otherwise well and meet discharge criteria but continue to have occasional episodes of apnea for prolonged period. However, this is a debatable practice as home apnea monitoring has not been shown to decrease the incidence of sudden infant death syndrome (SIDS).

Any infant having apnea should be evaluated for possible cause of apnea. Many neonatal conditions may manifest with apnea in neonates; hence, neonate should be evaluated for these conditions as appropriate. Apnea of prematurity (AOP) should always be a diagnosis of exclusion.

## Differential Diagnosis of Apnea of Prematurity

- *Temperature instability* Hypothermia, hyperthermia
- *Metabolic* Hypoglycemia, hypocalcemia, hyponatremia, hypernatremia, acidosis
- *Infections* Sepsis, pneumonia, UTI, meningitis
- *CNS* Intracranial hemorrhage, seizures, infections, other structural malformations
- *Cardiovascular* Hypertension, hypotension, hypovolemia, vagal tone, heart failure
- *Hematological* Anemia, polycythemia
- *Respiratory* RDS, pneumothorax, hypoxemia, hypercarbia, airway obstruction, BPD spells
- *Gastrointestinal* Necrotizing enterocolitis, GERD
- *Drugs* Intrapartum magnesium exposure, sedatives.

## MANAGEMENT OF APNEA

### General Measures

- *Maintain airway, breathing and circulation*
- *Avoid vigorous suctioning of oropharynx*
- *Position* Extreme flexion or extension of neck should be avoided. Prone positioning improves thoracoabdominal synchrony and stabilizes the chest wall and may reduce AOP. However, unsupervised prone nursing has been associated with an increased risk of SIDS; hence, an infant being nursed in prone position should not be left unattended and should be on continuous monitoring.
- *Kinesthetic stimulation* Tactile stimulation is the most common intervention offered to a neonate having an apneic episode. This simple intervention most likely works by generating excitatory, nonspecific neuronal activity in the brainstem center and stimulate respiratory activity. Due to same logic, some units use oscillating mattresses and various other ways to provide continuous kinesthetic stimulation to neonates having recurrent apnea.
- *Maintain euthermia* Hypothermia and hyperthermia both are risk factors for AOP and should be treated promptly.
- *Check and correct hypoglycemia, hypocalcemia and electrolyte imbalance*
- *Sensory stimulation* Avoid exposure to obnoxious odors as these lead to a decrease in respiratory drive. Pleasant odors, such as rose scent or smell of mother's milk elicit an increased respiratory drive.

## Pharmacological Treatment

### Methylxanthines

Methylxanthines are most commonly used medications for treatment of neonatal apnea. There is no definite consensus on when to start pharmacological treatment. Most often treatment

is started when apneic spells are recurring, nonresponsive to supportive measures or if an apneic spell requires bag and mask ventilation. There is no benefit of prophylactic use of xanthenes for prevention of apnea of prematurity.

**Methylxanthines** are central respiratory stimulants that increase CO<sub>2</sub> sensitivity and, hence, lead to improved tidal and minute volumes and blood gas values. These also increase diaphragmatic function and decrease muscle fatigue. The mechanism of these actions is competitive antagonism of adenosine receptors. Adenosine acts as an inhibitory neuroregulator in the central nervous system and is released during hypoxia. Theophylline and caffeine are two commonly available xanthine preparations for treatment of apnea in neonates.

**Theophylline** Theophylline is available in oral and intravenous preparations. The intravenous form is aminophylline, a complex of theophylline and ethylenediamine. Mean half-life of theophylline is approximately 30 hours. Treatment usually is initiated with a loading dose followed by maintenance therapy. The loading dose is 5–6 mg/kg, followed by 1–2 mg/kg every 8 hours. A therapeutic effect is seen at plasma concentration of at least 5 mg/L, although a target plasma concentration is around 10 mg/L. Plasma concentration of theophylline may vary widely at the same dosage levels, and therapeutic index is low, necessitating frequent monitoring and dose adjustments. Toxicity usually starts after plasma concentration of 20 mg/L. Common adverse effects include tachycardia, cardiac dysrhythmias, abdominal distention, feed intolerance, seizures, hyperglycemia and electrolyte imbalances.

**Caffeine** Caffeine is available for both oral and intravenous use and has some advantages over theophylline. It is associated with less adverse effects, and has long half-life, leading to once a day dosing. It has higher therapeutic index with wide margin of safety; hence, routine monitoring of drug level is not required. The recommended dose of caffeine citrate is 20 mg/kg loading, followed 24 hours later by 5.0 mg/kg IV or PO q 24 hours. If apnea recurs, maintenance dose may be increased stepwise, up to 12.5–15 mg/kg/day. Side effects are unusual at usual dose range. Commonly observed adverse effects are jitteriness, tachycardia and occasionally feed intolerance.

### Concerns with Methylxanthines

**Effect on neurological development** The methylxanthines are adenosine receptor antagonists. Adenosine is believed to be neuro-protective during ischemia. It is postulated that methylxanthines may actually worsen hypoxic tissue damage in infants at risk of recurrent hypoxemia. However, a large multicentric trial (CAP trial) has established safety of caffeine therapy in neonates with birth weight 500–1250 g. Caffeine therapy was associated with reduced incidence of BPD and lesser duration of mechanical ventilation. Five years follow-up of the study revealed no difference in the composite outcome of death or severe impairment but there was statistically significant improvement in motor coordination and visual perception in caffeine-treated group.

**Effect on growth** Another concern regarding use of methylxanthines is its effect on growth of preterm neonates. Methylxanthines increase oxygen consumption in preterm neonates by 20–25%. A single 5 mg/kg dose of theophylline increases energy expenditure by 15 kJ/kg per day; this may have an effect on growth of preterm infant. In CAP trial, daily weight gain of caffeine-treated infants was less during the first 3 weeks of therapy. However, there was no difference by 4 weeks age. By 18–24 months age, the mean percentiles for weight, height and head circumference did not differ between caffeine and placebo.

### Doxapram

Doxapram is another drug used for apnea in neonates. Mechanism of action appears to be related to stimulation of carotid

chemoreceptors at lower doses and to direct stimulation of central respiratory control neurons at higher doses. The intravenous loading dose for doxapram is 2.5–3.0 mg/kg over 15 min followed by a continuous infusion of 1.0 mg/kg titrated to the lowest responsive dose (maximum dose 2.5 mg/kg/h). At low doses as used in AOP, significant side effects are uncommon but increased blood pressure and other side effects of catecholamine stimulation can occur, including lowering seizure threshold, gastrointestinal disturbances and even heart block. A single small study on doxapram showed decrease in apnea in first 48 hours of initiation of medication; however, the effect was not sustained. There are concerns about safety of doxapram use in neonates. Doxapram has been shown to decrease the cerebral blood flow in preterm neonates and some studies have shown mental developmental delay with prolonged use of doxapram. In view of a lack of evidence for benefits and possible neurological toxicity, doxapram should not be used as primary therapy and should be kept as reserve drug for treatment of apnea.

## Nonpharmacological Measures

### Ventilation

Some premature infants continue to have apnea while on methylxanthine therapy. In these infants, use of nasal continuous positive airway pressure (CPAP) may reduce incidence and frequency of apnea. CPAP is hypothesized to work by several mechanisms, including improvement of PaO<sub>2</sub> by increasing FRC, splinting of the upper airway and stabilization of compliant chest wall of preterm neonates eliminating thoracoabdominal dyssynchrony. Potential adverse effects of CPAP include barotrauma, abdominal distension, feeding intolerance and local nasal trauma. CPAP should be considered if infant continues to have apnea while on xanthine therapy; there is no role of prophylactic CPAP for prevention of apnea of prematurity. If apnea persists on nasal CPAP, infant is intubated and put on invasive ventilation. Some investigators have suggested nasal intermittent positive pressure ventilation (NIPPV) as a missing link between nasal CPAP and invasive ventilation. Two trials have compared nasal CPAP to nasal IPPV. However, both trials have shown different results. One study showed no difference in apneas whereas the other showed NIPPV to be more effective in reducing apneas.

### Kangaroo Mother Care

Kangaroo mother care, also known as skin-to-skin contact, is a widely prevalent practice, where a hemodynamically stable neonate is kept in close contact with skin of mother/caregiver. However, the effect of this approach for the treatment of AOP remains controversial. A randomized controlled trial showed that infants receiving kangaroo care had fewer apneic and bradycardic events than those who did not receive kangaroo care. In another study, researchers found that apneic and bradycardic events were increased during kangaroo care.

### CO<sub>2</sub> Inhalation

A fall in CO<sub>2</sub> levels below a threshold leads to an apnea and a rise in CO<sub>2</sub> above the apnea threshold will reduce or abolish apnea. This has led researchers to investigate the role of CO<sub>2</sub> inhalation in prevention or treatment of apnea of prematurity. Recently, a randomized controlled trial of theophylline versus CO<sub>2</sub> inhalation for treatment of AOP showed that inhalation of a low CO<sub>2</sub> concentration (0.8%) in premature infants was as effective as theophylline in decreasing apnea. No adverse effects of CO<sub>2</sub> inhalation on cerebral blood flow velocity were observed. However, feasibility and long-term safety of this intervention is yet to be established and CO<sub>2</sub> inhalation still remains an experimental tool.

### Blood Transfusion

Anemia is associated with decreased oxygen content of blood and has been suggested to increase the risk of apnea. Neonates with idiopathic apnea and coexisting anemia are transfused with packed cells. Transfusion is usually considered if hematocrit is <25% and infant has episodes of apnea and bradycardia that are frequent or severe while on methylxanthine therapy. However, benefit of such practice is debated and studies have reported no difference in frequency of apnea before or after transfusion though one randomized trial of liberal or restrictive transfusion practices reported higher frequency of apnea in restrictive group.

### CONSEQUENCES OF NEONATAL APNEA

Brief apnea, which resolves quickly, may not be a threat to physiological well-being. A significant apnea is that associated with hypoxia, hypercarbia, bradycardia and changes in blood pressure. A prolonged apnea may lead to cerebral hypoperfusion, which may result in hypoxic-ischemic insult to developing brain of preterm infant. This initial hypoperfusion and hypoxia might be followed by a transient compensatory hyperperfusion with an associated potential reperfusion injury. These concerns warrant neurological follow-up of infants experiencing these events. However, the long-term consequences of recurrent apnea and bradycardia are difficult to ascertain due to confounding effect of coexistence of other common neurological morbidities.

Many studies have reported a relationship between number of apnea days and neurodevelopmental impairment. However, these studies did not establish whether apnea is a cause of or results from underlying cerebral dysfunction in preterm infants or if both apnea and lower neurodevelopmental indices have a common underlying cause.

### IN A NUTSHELL

1. Apnea is a common condition in preterm neonates, usually caused by an immaturity of respiratory control in brainstem.
2. Apnea of prematurity is most common diagnosis for apnea in neonates. However, it should be a diagnosis of exclusion, after evaluation of other differentials for apnea.
3. Xanthines are mainstay of pharmacotherapy for apnea.

## Chapter 17.3

# Neonatal Ventilation

Sourabh Dutta

The advent of neonatal intensive care has also resulted in improved respiratory support for neonates and consequently improved survival. But neonates have a physiology distinct from infants and adults and more so if they are born preterm. It is, therefore, important that pediatricians understand the physiology of neonatal ventilation.

### WHAT ARE VENTILATORS?

The most commonly used basic neonatal ventilators are the so-called *timed cycled*, *continuous flow*, *pressure-controlled* ventilators (**Fig. 1**). An endotracheal tube is the interface device through which the ventilator delivers gases to the newborn infant. *Time-cycled* means that the ventilator switches from inspiration to expiration based on a set time. *Pressure-controlled* means that the physician decides the pressure that is to be delivered and the tidal volume is a measured parameter. This is in contrast to *volume-controlled* ventilation where the physician decides the volume to be delivered. *Continuous flow* refers to flow of gases in the ventilator circuit. While the flow of gases in the ventilator circuit is continuous, the flow of gases through the endotracheal tube transiently ceases and reverses direction in each respiratory cycle.

### VENTILATOR PARAMETERS

In conventional ventilation, there are six parameters we are primarily concerned with (**Table 1**).

#### Gas Flow

Gas flows from a region of high pressure to low pressure. This is shown graphically in **Figure 2**.

The flow of gases is governed by Poiseuille's law which states:

$$\text{Flow} = [\pi \times (P_1 - P_2) \times \text{radius}^4] \div (8 \times \text{viscosity} \times \text{length})$$

Therefore, the flow of gases through an endotracheal tube increases when the difference between  $P_1$  and  $P_2$  increases, when the radius of the endotracheal tube increases, when the length of the endotracheal tube decreases and when the viscosity of the gas mixture decreases. The flow of gases through the endotracheal tube decreases when the pressure difference decreases, the radius decreases, the length of endotracheal tube increases and the viscosity of the gas mixture increases. For all practical purposes, the viscosity of the gas mixture is a constant.

### Spontaneous Breathing versus Ventilator Breaths

#### Spontaneous Breathing

To understand how a ventilator works, it is important to understand how spontaneous breathing takes place. At the onset of a spontaneous breath, the rib cage moves outwards and the diaphragm moves downwards to create a negative intrathoracic pressure with respect to the atmospheric pressure. This difference in pressure results in the flow of atmospheric air into the lungs. The magnitude of flow depends on the pressure gradient, the radius of the glottis and the length of the air passages. During exhalation, the rib cage and diaphragm move inwards to create a slight positive intrathoracic pressure and this results in the flow of gases from the lungs out through the nares into the atmosphere. The glottis partially closes during normal breathing. This creates a physiological positive end-expiratory pressure (PEEP) which is

around 3 cm  $H_2O$ . The normal respiratory rate (RR) ranges from 20 to 60 breaths per minute.

#### Ventilator Breaths

Unlike spontaneous breathing, which is negative pressure ventilation, the mechanical ventilation provided by a ventilator is positive pressure ventilation. The baseline pressure in the ventilator circuit, endotracheal tube and air passages of the neonate is the PEEP. Periodically, the pressure inside the ventilator circuit is rapidly increased to reach the peak inspiratory pressure (PIP). This creates a pressure gradient (PIP-PEEP) which drives gases from the ventilator circuit through the endotracheal tube into the lungs of the newborn infant. If the ventilator pressure is increased almost instantaneously to reach the PIP, it is called square wave ventilation, whereas if the ventilator pressure is made to rise slowly, it is called sine wave ventilation.

The flow of gases continues till such time that the pressure inside the lungs equilibrates with the pressure inside the ventilator circuit (PIP). The magnitude of the flow through the endotracheal tube is dependent upon the pressure gradient, the internal radius of the endotracheal tube and the combined length of the endotracheal tube and the air passages of the neonate. The duration over which the pressure in the ventilator circuit rises and is held at the level of the PIP is called inspiratory time ( $T_i$ ). Once the  $T_i$  is complete, in a time-cycled ventilator, the pressure inside the ventilator circuit reduces instantaneously to the level of PEEP. Since the pressure inside the lungs is still at the level of PIP, the pressure gradient now reverses and gases flow out of the lungs into the ventilator circuit. The flow continues till such time that the pressure in the lungs equilibrates with that of the ventilator circuit (PEEP). These phenomena are shown graphically in **Figures 3A and B**. Note that the flow of gases into the lungs does not occur throughout the  $T_i$ ; and, similarly, the flow of gases out of the lungs does not go on throughout the expiratory time ( $T_e$ ), because in both instances pressure equilibrates before the  $T_i$  and  $T_e$  are completed. Spontaneous breathing can continue superimposed on the mechanical breath cycle.

#### Compliance

Compliance is defined as the change in volume per unit change in pressure (see pressure-volume curve in **Figure 4**). The change in pressure over one ventilator cycle ( $\Delta P$ ) is essentially PIP minus PEEP. The change in volume during one breath is the ventilator tidal volume. The normal tidal volume is 4–8 mL/kg, with the median figure being around 5 mL/kg. Therefore, compliance is the tidal volume divided by the difference between PIP and PEEP. Respiratory distress syndrome (RDS) is a typical example of a disease with low compliance. In RDS, a given change in pressure results in a lower tidal volume compared to a normal lung.

#### Resistance

Just as the resistance of an electric wire is equal to the voltage difference divided by the flow of current, the resistance of a tube to the flow of gases is equal to the pressure difference divided by the flow rate of gases. We have already seen that the flow of gases is directly proportionate to the pressure difference and radius to the 4th order of magnitude and inversely proportionate to the length (with viscosity being a constant). Thus, resistance is directly proportionate to the length of the tube and inversely proportionate to the radius to the 4th order of magnitude. Since the radius is raised to the 4th power, minor changes in the internal radius of the endotracheal tube or air passages (due to secretions, blood or fluid) can result in huge changes in resistance.

#### Time Constant

We have seen earlier that it takes some time for pressure to equilibrate between the ventilator circuit and the lungs (i.e., the alveoli). The pressure changes at the level of the alveoli seem

**Figure 1** Ventilator breaths and spontaneous breaths on continuous flow

**Figure 2** Factors affecting flow of gases from high-pressure end to low-pressure end of a tube

to lag behind the pressure change in the ventilator. The term 'time constant' gives us an idea of the time taken for pressure to equilibrate between the proximal airway and the alveoli.

1 Time constant = Compliance  $\times$  Resistance.

At the onset of inspiration, there is a certain pressure difference between the proximal airway and the alveoli. It takes 1 time constant for the rise in alveolar pressure to cover 63% of this pressure difference. Once 63% of the pressure difference is achieved, it requires another time constant for the alveolar pressure to reach 63% of the remaining pressure difference and so on. Thus, the equilibration of pressures is not a linear process but it follows first-order kinetics. As can be seen in **Figure 5**, it takes approximately 3 time constants to achieve 95% equilibration. Therefore, the  $T_i$  on the ventilator is generally set at 3 times the expected  $T_i$  constant. 95% equilibration is considered to be safe because extending the  $T_i$  beyond 3 time constants may result in overdistention.

A mirror image process occurs during expiration. The time constant during expiration is longer than inspiration because the radii of distal airways narrow during expiration, and the glottis remains partially closed during expiration. This is the reason why—both during spontaneous breathing as well as during mechanical ventilation—the time taken for expiration is longer than the time taken for inspiration.

If the  $T_i$  is set at less than 3  $T_i$  constants, it results in delivery of inadequate tidal volume; whereas, if it is set at a value greater than 3 time constants, it results in overdistention of the alveoli. If the  $T_e$  is set at less than 3  $T_e$  constants, it results in incomplete emptying of the alveoli and gas trapping within the lungs. Gas trapping over several mechanical breaths results in an unintended pressure

buildup at the end of expiration and this unintended pressure is called inadvertent PEEP.

A normal newborn lung has a compliance of 1.5–2 mL/cm  $H_2O$ /kg and a normal term newborn lung has a resistance of 0.03 cm  $H_2O$ /mL/s. A full-term 3 kg neonate will have a compliance of approximately 5 mL/cm  $H_2O$ . Therefore, the normal time constant is approximately 0.15s.

### Mean Airway Pressure

The maintenance of adequate levels of partial pressure of oxygen in arterial blood ( $PaO_2$ ) is called oxygenation. Oxygenation is proportionate to  $FiO_2$  and mean airway pressure (MAP). MAP is calculated by the area under the pressure-time curve per second of the respiratory cycle (**Fig. 6**). The area under the pressure-time curve of one respiratory cycle is  $(PIP \times T_i) + (PEEP \times T_e)$ . This is easy to understand because each of the boxes (the box made by the PIP and the box made by the PEEP) is rectangle. The time taken for each respiratory cycle is  $T_i + T_e$ .

Thus,  $MAP = [(PIP \times T_i) + (PEEP \times T_e)] \div [T_i + T_e]$ .

In sine wave ventilation, the PIP box is not a rectangle, and to correct for that, a constant  $k$  is included in the equation which is always less than 1.

The modified formula is:

$$MAP = [(k \times PIP \times T_i) + (PEEP \times T_e)] \div [T_i + T_e]$$

It is evident from this formula that the following interventions (in decreasing order of effectiveness) can increase the MAP:

- Increasing the PEEP
- Increasing the PIP
- Increasing the  $T_i$
- Shifting from sine wave to square wave ventilation
- Decreasing the  $T_i + T_e$ ; i.e., increasing the RR. Among all these parameters, increasing the RR has the least effect on MAP.

### Minute Ventilation

The removal of carbon dioxide from the lungs depends directly upon the minute ventilation.

$$\text{Minute ventilation} = \text{Tidal volume} \times \text{RR}$$

As can be seen from the pressure-volume curve in **Figure 4**, the greater the difference between PIP and PEEP (i.e.,  $\Delta P$ ), the greater is the tidal volume. Therefore, tidal volume can be increased either by increasing the PIP or by decreasing the PEEP or by doing both simultaneously. Minute ventilation can be increased by increasing the  $\Delta P$  or increasing the RR.

### MODES OF VENTILATION

Modern day ventilators have a bewildering array of modes of ventilation. It will not be possible to cover all modes in a textbook for postgraduates. This chapter will attempt to touch upon intermittent mandatory ventilation (IMV), patients triggered modes of ventilation such as synchronized intermittent mandatory

**Table 1** Parameters adjustable on ventilators

Parameter	Abbreviation	Explanation
Peak inspiratory pressure	PIP	Maximum pressure achieved by the ventilator during the inspiratory phase
Positive end-expiratory pressure	PEEP	Pressure maintained by the ventilator during the expiratory phase. This is the minimum pressure achieved during the respiratory cycle
Fraction of inspired oxygen	$FiO_2$	Fraction of inspired gases that comprises of oxygen
Inspiratory time	$T_i$	Time available for the ventilator to push gases into the lungs during the inspiratory phase of the respiratory cycle
Respiratory rate	RR	The number of mechanical breaths provided by the ventilator over 1 min. The expiratory time ( $T_e$ ) can be derived from the RR and $T_i$
Flow	F	The liters of gas that flow through the ventilator circuit per minute

ventilation (SIMV), assist-control ventilation (ACV) and pressure support ventilation (PSV).

### Intermittent Mandatory Ventilation

In IMV, the mechanical breaths are provided at fixed intervals by the ventilator (intermittent) and the number of such breaths is also fixed (mandatory). As shown in **Figure 7**, in IMV, there is no synchronization of the spontaneous breaths of the patient (shown as blue colored breaths: A to G) with the ventilator breaths. There is dyssynchrony with respect to the start of each ventilator breath, the end of each ventilator breath and the total number of ventilator breaths. If any spontaneous breath happens to coincide with a ventilator breath, it is just a matter of random chance. Note that the start of the spontaneous breath A happens to coincide with the start of a mechanical ventilator breath and the end of spontaneous breath F happens to coincide with the end of a ventilator breath.

Note that the inspiratory phase of spontaneous breath C is superimposed on the expiratory phase of a mechanical breath, whereas

the expiratory phase of spontaneous breath D is superimposed on the inspiratory phase of a mechanical breath. When this form of dyssynchrony occurs, it results in sudden changes in intrapulmonary pressure; and may predispose to air leaks and increased work of breathing. Spontaneous breaths B and E are superimposed upon mechanical breaths. This results in an inadvertently high-tidal volume which can result in air leaks. Spontaneous breath G is superimposed upon the PEEP. This is akin to providing endotracheal continuous positive airway pressure (CPAP) in which the patient has to work hard to draw gases through a narrow tube.

### Triggered Modes of Ventilation

#### *Synchronized Intermittent Mandatory Ventilation*

In SIMV, the number of mechanical breaths is mandatory but wherever possible the onset of a mechanical breath is made to synchronize with a spontaneous breath. Each mandatory breath has a trigger window prior to the scheduled onset of the mandatory breath. If a spontaneous breath is initiated within this trigger window period, it triggers off a mechanical breath. Spontaneous breaths occurring in excess of the mandatory rate will not trigger a mechanical breath. If the patient is apneic, the ventilator simply delivers the fixed number of mandatory breaths at the scheduled intervals. In SIMV, the physician fixes the number of mandatory breaths (RR), PIP, PEEP,  $T_i$ , flow,  $FiO_2$  and the trigger sensitivity. The onset of the mandatory breaths is decided by the patient. The total number of ventilator breaths is not decided by the patient.

#### *Assisted Controlled Ventilation*

Every spontaneous breath triggers a mechanical breath that supports the spontaneous breath. This is the assist component of ventilation. The physician fixes the PIP, PEEP,  $T_i$ , flow,  $FiO_2$  and the trigger sensitivity. To cater to a situation where the patient may

**Table 2** Adjusting ventilator settings using blood gas measurements

$PaO_2$	$PaCO_2$	Change in single parameter required (and reasons thereof)	Alternate option (and situation where indicated)
Hyperoxia	Normal	Decrease $FiO_2$ (to normalize oxygenation without affecting minute ventilation)	Decrease PIP and PEEP by equal amount keeping $\Delta P$ constant (in situations where ventilator pressures are high and $FiO_2$ is already low)
Hypoxia	Normal	Increase $FiO_2$ (to normalize oxygenation without affecting minute ventilation)	Increase PIP and PEEP by equal amount keeping $\Delta P$ constant (in situations where ventilator pressures are low and $FiO_2$ is already high)
Normal	Hypercarbia	Increase RR (to normalize minute ventilation with no or minimal effect on oxygenation)	Increase PIP and decrease $FiO_2$ to offset the effect of PIP on oxygenation (in situations where tidal volume is low and should be increased to normalize minute ventilation)
Normal	Hypocarbia	Decrease RR (to normalize minute ventilation with no or minimal effect on oxygenation)	Decrease PIP and increase $FiO_2$ to offset the effect of PIP on oxygenation (in situations where the tidal volume is high and should be decreased to normalize minute ventilation)
Hyperoxia	Hypercarbia	Decrease PEEP (to decrease MAP and increase $\Delta P$ )	Decrease $FiO_2$ and increase RR (in situations where lung is underinflated; decreasing PEEP may cause derecruitment or tidal volume is already high)
Hyperoxia	Hypocarbia	Decrease PIP (to decrease MAP and decrease $\Delta P$ )	Decrease $FiO_2$ and decrease RR (in situations where tidal volume is already low)
Hypoxia	Hypercarbia	Increase PIP (to increase MAP and increase $\Delta P$ )	Increase $FiO_2$ and increase RR (in situations where tidal volume is already high)
Hypoxia	Hypocarbia	Increase PEEP (to increase MAP and decrease $\Delta P$ )	Increase $FiO_2$ and decrease RR (in situations where tidal volume is already low or lung is hyperinflated)

Abbreviations:  $PaO_2$ , partial pressure of oxygen in arterial blood;  $PaCO_2$ , partial pressure of carbon dioxide in arterial blood;  $FiO_2$ , fraction of inspired oxygen; PIP, peak inspiratory pressure; PEEP, positive end-expiratory pressure; RR, respiratory rate; MAP, mean airway pressure.

become apneic, there is a provision for a backup rate of mechanical breaths—this is the control component of ventilation. The control rate is set lower than the usual RR of the neonate and is only intended as a safety measure in case of apnea. In ACV, the onset of ventilator breaths and the total number of ventilator breaths are decided by the patient.

### Pressure Support Ventilation

Pressure support ventilation originated in adult ventilation as a means to decrease the work of breathing in intubated patients who were receiving CPAP. Spontaneous breathing on endotracheal CPAP is like breathing through a straw because the tidal volume of the spontaneous breath is drawn through a narrow endotracheal tube. In PSV, every spontaneous breath is supported by a so-called pressure boost which raises the pressure to a level lower than the usual PIP that is provided in mechanical ventilation. The purpose of this pressure boost is simply to overcome the work of breathing and not to provide the entire tidal volume via the mechanical breath. The patient is expected to generate the tidal volume. The onset of the PSV breath is triggered by the patient. An additional unique feature of PSV is that the ventilator measures the spontaneous inspiratory flow rate of the patient in real-time and terminates the mechanical breath when the patient's inspiratory flow rate drops to less than a certain fraction (often 15%) of the peak inspiratory flow rate. The drop in flow rate to less than 15% is an indicator to the ventilator that the patient spontaneous breath is about to finish. Thus, in PSV, the onset of ventilator breaths, the number of ventilator breaths and the Ti of ventilator breaths are decided by the patient.

## VENTILATOR SETTINGS

### Initial Settings

Three common clinical conditions—apnea of prematurity, RDS and meconium aspiration syndrome (MAS) will be used to exemplify the basis for selecting the initial ventilator settings.

#### Apnea

In apnea of prematurity, the lungs are essentially normal. The presence of an endotracheal tube bypasses the glottis. As discussed earlier, in spontaneous breathing, the partially closed glottis generates a physiological PEEP of 3 cm H<sub>2</sub>O. In apnea ventilation, the PEEP should, therefore, be set at 3 cm H<sub>2</sub>O. The time constant of a normal neonatal lung is approximately 0.15s. Therefore, the Ti should be set at 0.45s. To achieve a tidal volume of 5–10 mL/kg, the PIP required would be approximately 7–10 cm H<sub>2</sub>O. This can be derived from the fact that the normal compliance is 1.5–2 mL/cm H<sub>2</sub>O/kg and compliance equals  $\Delta V/\Delta P$ . FiO<sub>2</sub> should be set at 0.21 because the transfer of oxygen across the lungs into the pulmonary vasculature is normal. The RR must be set at 20/min which is the lower limit of normal.

#### Respiratory Distress Syndrome

The functional residual capacity (FRC) of a neonatal lung with RDS is lower than a normal lung. To restore the FRC, the PEEP should be approximately 5 cm H<sub>2</sub>O. The typical compliance of a neonatal lung with RDS drops to approximately 25% of that of a normal lung. On plugging in the values, the typical starting PIP to achieve a tidal volume of 5 mL/kg in a neonate with RDS is 15 cm H<sub>2</sub>O. The lungs are stiffer in a neonate with RDS; hence, the compliance is less. This is partly counterbalanced by the increased resistance in a premature baby because of the narrow airways. The net result is that the time constant is lower than in a normal lung. The Ti required in RDS is generally varies between 0.3s and 0.35s. The FiO<sub>2</sub> has to be adjusted to maintain normal saturation. Higher RRs (around 50–60/min) are recommended to decrease lung injury.

### Meconium Aspiration Syndrome

Meconium aspiration syndrome is characterized by a combination of areas of hyperinflation and areas of atelectasis. The PEEP is selected anywhere in the range of 3–5 cm H<sub>2</sub>O, depending on whether hyperinflation or atelectasis is dominant. Meconium partially blocks the air passages and increases bronchial hyperactivity; therefore, MAS behaves like an obstructive lung disease with increased airway resistance. This is counterbalanced by some decrease in compliance because of secondary deactivation of surfactant. The net result is that the time constant is longer than in the case of RDS. As in the case of any obstructive lung disease, the Te constant is affected out of proportion to the Ti constant. To allow for adequate Te and prevent gas trapping, the RR has to be maintained in the range of 40–45/min. The Ti is limited to 0.4s leaving the rest of the respiratory cycle for the Te. Persistent pulmonary hypertension of the newborn (PPHN) is an important complication of MAS in the initial phase of the disease. To prevent PPHN, it is important to avoid hypercarbia and hypoxia. Therefore, adequate minute ventilation and FiO<sub>2</sub> are required.

### Adjustment of Settings

Ventilator settings are adjusted based upon arterial blood gas findings (Table 2), clinical findings, pulmonary functions and the expected course of the disease.

#### Based on Arterial Blood Gases

We can easily derive the ventilator changes required for different combinations of PaO<sub>2</sub> and partial pressure of carbon dioxide in arterial blood (PaCO<sub>2</sub>) from what we have learnt in the sections on oxygenation and minute ventilation. The guiding principle is that a change in a single parameter is generally preferred to making changes in two or more parameters simultaneously, unless there are compelling reasons to make two changes.

### Reducing Ventilator Support

The prerequisites for reducing ventilator support include improvement in the basic disease, stable ventilator settings for about 8–12 hours and acceptable blood gas values. It is a good principle to reduce parameters which are associated with more barotrauma and volutrauma such as the PIP. To be able to extubate the baby, the infant must have good spontaneous breathing effort, must be off sedation, and must have manageable secretions.

## MORE ON THIS TOPIC

- Davis RP, Mychaliska GB. Neonatal pulmonary physiology. *Semin Pediatr Surg.* 2013;22:179–84.
- Goldsmith JP, Karotkin EH. Assisted Ventilation of the Neonate. 5th ed. Philadelphia: Elsevier; 2011.
- Khilnani P. Pediatric and Neonatal Mechanical Ventilation, 2nd ed. New Delhi: Jaypee Brothers Medical Publishers; 2011.

### IN A NUTSHELL

1. The ventilator parameters that are usually adjusted to compensate for changes in pulmonary mechanics include PIP, PEEP, FiO<sub>2</sub>, Ti, rate and gas flow.
2. The patient triggered modes of ventilation include SIMV, ACV and PSV.
3. Ventilator adjustments are based on a combination of clinical assessment, blood gas values and chest skiagrams.
4. Reduction of ventilator support needs the basic disease to be improving, stable blood gases, good spontaneous breathing efforts by the baby, and manageable secretions.

## Chapter 17.4

# Hyaline Membrane Disease

Praveen Kumar, Anuj Bhatti

Hyaline membrane disease (HMD) is the most important cause of respiratory distress in preterm infants. Untreated, it carries a high mortality and morbidity. Advancements in neonatal intensive care, respiratory support and availability of surfactant replacement therapy (SRT) have brought down the mortality and morbidity dramatically in the developed world. However, it still is an antecedent of serious morbidity in extremely low birthweight infants.

Hyaline membrane disease is named so because of the appearance of pinkish waxy hyaline membranes composed of fibrinous material, proteins and dead cells which are seen to line the collapsed alveoli of infants dying from this disease. The term is often used synonymously and interchangeably with respiratory distress syndrome (RDS) which is a clinical diagnosis.

## EPIDEMIOLOGY

Hyaline membrane disease is typically a disease of preterm infants as it is primarily due to the deficiency of surfactant and structural immaturity of the lung related to prematurity. The incidence of HMD is inversely related to gestation. It is 60% in less than 30 weeks of gestation, 43% in 30–34 weeks of gestation and 5–6% in greater than 34 weeks of gestation. This is because of the progressive maturation of the developing lung and increasing surfactant production with advancing gestation. Other risk factors associated with increased incidence of HMD are perinatal asphyxia, maternal diabetes, lack of labor, absence of antenatal steroid administration and male gender. Small for gestational age infants as well as infants exposed to maternal chorioamnionitis have more chances of severe and chronic lung damage. Relatively mature and term infants can occasionally develop HMD due to genetic conditions causing deficient production of surfactant proteins.

## PATHOPHYSIOLOGY

The central feature of HMD is surfactant deficiency, which results in increased surface tension. Surface tension is a contractive tendency of the surface of a liquid that allows it to resist an external force. In other words, at air-liquid interface, the molecules of the liquid

are always under tension with a tendency to contract; so that they form a sphere of minimal radius. According to *Laplace's law* (Fig. 1), the pressure required to inflate a sphere is directly proportional to surface tension and inversely proportional to the radius of the bubble. If we apply this corollary to the inflation of alveoli at birth, the work done by the infant will be more if the surface tension is increased and the alveoli are collapsed (decreased radius). In other words, the compliance (distensibility) of the lung tissue will be less, i.e., pressure required for a unit change in volume of alveoli will be more (compliance = change in volume/change in pressure). Lung surfactant is required to reduce the surface tension at the air-liquid interface. Moreover, as the radius of the bubble decreases, the need for the surfactant to reduce surface tension increases. In other words, surfactant helps to maintain functional residual capacity (FRC). FRC is the volume of the air left in lungs after normal expiration. In normal lung, at end of expiration there is still air present in the lungs. In infants with HMD, alveoli collapse at the end of expiration. So, during the next breath, higher pressures need to be generated resulting in increased work of breathing.

The production of surfactant starts in type II pneumocytes during the terminal sac stage of lung development. Surfactant in the type II pneumocytes appears in the form of lamellar bodies in the cytoplasm at about 20 weeks of gestation. These lamellar bodies are secreted into the alveolar fluid to form tubular myelins. These are then adsorbed at the alveolar surface liquid-air interface. Surfactant proteins B and C (SP-B and SP-C) are essential for transition into monolayer at air-liquid interface. Absence of SP-B and SP-C is associated with fatal neonatal respiratory distress at birth (pulmonary alveolar proteinosis). Pulmonary surfactant is composed of lipids (90%) and protein (10%) (Fig. 2). The main phospholipid in the surfactant is dipalmitoylphosphatidylcholine (DPPC), also called lecithin. It decreases the surface tension because of its unique structure which consists of a hydrophilic head and a hydrophobic tail (Fig. 3). Lecithin, being a saturated lipid, is in gel form at body temperature. So, for efficient adsorption at the air-liquid interface, it has to be converted into fluid form. This is helped by the presence of other unsaturated lipids. Other lipids help in the uptake, spreading and redistribution at smallest airways.

Lung injury due to positive pressure ventilation at birth or later is also an important contributory factor in the evolution of HMD. Positive pressure or overstretching of alveoli causes lung fluid to leak into the alveoli, which inactivates the surfactant. Establishing and maintaining appropriate FRC immediately after birth noninvasively (*keeping the lung open*) can minimize this injury substantially.

Figure 2 Surfactant composition

**Figure 3** Air-liquid interface with surfactant. Lecithin (DPPC) gets adsorbed at air-liquid interface with hydrophilic head (red) towards the liquid medium and hydrophobic tail (green) towards the air. Once adsorbed, the hydrophilic tails repel each other, thus decreasing the surface tension

## CLINICAL FEATURES

Tachypnea (respiratory rate more than 60/min), increased work of breathing and grunt are the cardinal features of HMD. The onset of the symptoms could be anytime soon after birth to within 6 hours after birth. Surfactant deficient lungs of the preterm baby require larger negative intrathoracic pressure to reopen collapsed alveoli during the phase of inspiration. This leads to use of accessory muscles of respiration leading to intercostal retractions, nasal flaring and head bobbing. Because the rib cage in premature infants is very compliant (soft), the sternum may deeply retract during inspiration. During expiration, the infant tries to maintain FRC (to prevent alveolar collapse) by expiring through partially closed glottis. This is manifested as grunt. Cyanosis or low oxygen saturation may be present due to inadequate oxygenation. Infant can appear pale due to acidosis because of inadequate removal of carbon dioxide (respiratory acidosis). This may be confused with the pallor due to blood loss at delivery. Lethargy and apnea can result due to increase work of breathing, cyanosis and acidosis. Extremely low birthweight and asphyxiated babies with HMD may developed apnea immediately following birth rather than progressing through above signs and symptoms. The progress of respiratory distress can be prospectively followed by using objective scoring systems like Silverman-Anderson and Downes' scores outlined in Chapter 17.1.

## Clinical Course

Typically, the disease presents within 6 hours of birth. If left untreated, the disease worsens for 24–48 hours and then begins to improve as the natural surfactant production begins. The infant, if survives, usually recovers in 5–7 days. Very preterm infants will not be able to make it without support. If surfactant is given and/or early continuous positive airway pressure (CPAP) is applied, the clinical course is altered and recovery is faster.

## INVESTIGATIONS

### Chest Radiograph

The classical findings in HMD include low volume lungs, reticulogranular shadows, air bronchograms, diffuse ground glass appearance and complete white-out (**Fig. 4**). The reticulogranular pattern is because of microatelectasis in the background of open small airways. Large airways beyond second- and third-generation branches are more visible due to engorged peribronchial lymphatics and fluid-filled or collapsed alveoli, resulting in air bronchograms. Widespread collapse of lung fields can lead to diffuse and homogeneous dense shadows. These radiographic findings are usually present shortly after birth but occasionally do not reach maximum severity until 12–24 hours of life. Moreover, the

**Figure 4** Chest X-ray of an infant with hyaline membrane disease (HMD): low lung volumes, homogeneous opacities, ground glass appearance. Air bronchograms can be seen (white arrow)

classical radiological findings may not be observed if exogenous surfactant has been given and/or adequate positive end-expiratory pressure (PEEP) has been applied right from the beginning.

## Arterial Blood Gas Analysis

Blood gas is essential because with clinical assessment and pulse oximetry alone, one would not be able to assess partial arterial carbon dioxide pressure ( $\text{PaCO}_2$ ) and pH. In the initial stages of respiratory distress, arterial blood gas (ABG) may be normal or show hypoxia with normal  $\text{PaCO}_2$  (sometimes  $\text{PaCO}_2$  may be decreased in early stages due to severe tachypnea). As the respiratory distress worsens and baby tires down,  $\text{PaCO}_2$  starts to increase, leading to respiratory acidosis. There is also a component of metabolic acidosis due to increased work of breathing. Furthermore, as the oxygen delivery to the tissues is compromised, lactic acid may accumulate, leading to mixed respiratory and metabolic acidosis.

## Assessment of Gas Exchange

Though the blood gas parameters indicate oxygenation and ventilation at a single point of time, these parameters alone are not sufficient to evaluate gas exchange. Interpretation of partial arterial oxygen pressure ( $\text{PaO}_2$ ) without fractional inspired oxygen concentration ( $\text{FiO}_2$ ) is misleading. Hence, the gas exchange should be assessed using: (1) alveolar-arterial oxygen gradient ( $\text{A-aDO}_2$ ); (2) arterial to alveolar oxygen ratio (a/A ratio); and (3) oxygenation index (OI).

**Alveolar-arterial oxygen diffusion gradient** This is calculated as shown below:

$$\begin{aligned} \text{A-aDO}_2 &= \text{PAO}_2 - \text{PaO}_2 \text{ (P alveolar - P arterial oxygen pressure)} \\ &= [\text{PiO}_2 - \text{PACO}_2] - \text{PaO}_2 \\ &= [(\text{PB} - \text{PW}) \times \text{FiO}_2 - \text{PACO}_2] - \text{PaO}_2 \\ &= [(760 - 47) \times \text{FiO}_2 - \text{PACO}_2] - \text{PaO}_2 \end{aligned}$$

( $\text{PAO}_2$ , partial alveolar oxygen pressure;  $\text{PaO}_2$ , partial arterial oxygen pressure;  $\text{PiO}_2$ , partial inspired oxygen pressure; PB, barometric pressure; PW, water vapour pressure;  $\text{FiO}_2$ , fractional inspired oxygen concentration;  $\text{PACO}_2$ , partial alveolar carbon dioxide pressure;  $\text{PaCO}_2$ , partial arterial carbon dioxide pressure.)

Normally it ranges between 5 and 15 while breathing room air.  $\text{A-aDO}_2$  is considered to be abnormal if it is more than 40.

**Arterial to alveolar oxygen ratio** Ratio of  $\text{PaO}_2$  to partial alveolar oxygen pressure ( $\text{PAO}_2$ ). It is considered to be a better indicator of

gas exchange as the ratio is usually not affected by changes in  $\text{FiO}_2$ . The interpretation of this ratio is depicted below:

1. Greater than 0.8—normal
2. Less than 0.6—indicates need for oxygen therapy
3. Less than 0.15—severe hypoxemia.

**Oxygenation index** Recommended in babies who are mechanically ventilated as this index includes mean airway pressure (MAP).

$$\text{OI} = (\text{MAP} \times \text{FiO}_2) / \text{PaO}_2$$

The interpretation of this index is as below:

1. OI 25–40—severe respiratory failure; mortality risk is 50–60%
2. OI greater than 40—mortality risk is greater than 80%.

### Gastric Aspirate Shake Test

This is useful in assessing the risk of RDS in neonates with respiratory distress who are less than 34 weeks of gestation or have risk factors for RDS. In a glass test tube with dimensions of 82 mm × 10.25 mm and 4 mL capacity, 0.5 mL of gastric aspirate is taken and mixed with 0.5 mL of absolute alcohol. The tube is shaken vigorously for 15 sec and allowed to stand for 15 min. If at least one complete rim of bubbles is present all the way round the meniscus, the risk of RDS is less than 1%, whereas complete absence of bubbles is associated with a 50–60% risk. Shake test interpretation is as follows:

- Negative test is no bubbles
- 1+ is very small bubbles in the meniscus extending one-third or less of distance around the test tube
- 2+ is single rim of bubbles extending one-third to all around the test tube
- 3+ is a rim of bubbles all the way around the test tube with a double row in some areas
- 4+ is a double row or more of bubbles all the way around the test tube.

3+ and 4+ indicate adequate lung surfactant. The shake test is only an ancillary investigation and the decision to give surfactant should be based upon the severity of respiratory distress and oxygen requirement.

### Investigations for Sepsis

As it may be impossible to rule out infection at the onset in a sick preterm infant, most infants would undergo a blood culture and sepsis screen which may include C-reactive protein (CRP), micro-ESR, total leukocyte count (TLC), absolute neutrophil count (ANC) and immature to total leukocyte ratio (ITR).

### Other Investigations

Blood glucose, ionized calcium, hemoglobin (Hb) or packed cell volume (PCV), electrolytes.

### DIFFERENTIAL DIAGNOSIS

Congenital pneumonia is the closest differential diagnosis. Onset of pneumonia can be soon after birth but could be delayed beyond 6 hours. Pneumonia and HMD may also coexist (pneumonia can further lead to secondary surfactant deficiency). Maternal history of clinical and histological chorioamnionitis can point towards the differential diagnosis of pneumonia. Moreover, pneumonia can present with inhomogeneous shadows in the chest X-ray as against the typical homogeneous shadows seen in HMD (**Fig. 5**). Transient tachypnea of the newborn usually presents with mild tachypnea without retractions or grunt and resolves within 24–48 hours of life. The chest X-ray shows adequate to mildly increased lung volume with prominent fissures, streaky opacities and occasionally small effusions (**Fig. 6**). Obstructive total anomalous pulmonary venous return can have cyanosis with silent tachypnea and chest X-ray may mimic HMD.

**Figure 5** Chest X-ray of pneumonia: normal lung volumes, nonhomogeneous and patchy opacities

**Figure 6** Chest X-ray of infant with transient tachypnea of the newborn (TTNB): normal lung volumes, prominent major fissure and streaky opacities

### MANAGEMENT

#### Delivery Room Management

Special considerations should be made in the resuscitation of extremely low birthweight babies. For transition from fetal to neonatal life, newborn must replace lung fluid with air, establishing FRC in the lung. This is very difficult for the extreme preterm infant. So, during the resuscitation, the aim should be to *open the lungs* and subsequently *keep the lungs open* along with adequate oxygenation. This can be achieved by using devices which can provide CPAP or PEEP. These ventilation devices include: T-piece

resuscitator, flow inflating bag or a CPAP device. Recent cumulative evidence suggests that these infants should be placed on CPAP immediately after birth instead of intubation or leaving them on oxygen alone. Such a strategy reduces the need for surfactant and mechanical ventilation. There is also a reduction in the combined outcome of death or bronchopulmonary dysplasia (BPD).

### Initial Respiratory Support

The initial support can be in the form of oxygen alone, CPAP or mechanical ventilation. Early CPAP is the first choice of support. One should aim to avoid intubation as far as possible as intubation is the single most important factor leading to BPD.

#### Nasal Continuous Positive Airway Pressure

Continuous positive airway pressure helps in keeping the lungs (alveoli) inflated, especially during the phase of expiration. It should be kept in mind that CPAP works only in spontaneously breathing infants and will not provide inflating pressure (pressure required to inhale till maximum spontaneous inspiration). The system consists of a heated and humidified blended gas source, a nasal interface, a patient circuit and the pressure-generation apparatus (Fig. 7). As flow of gases is very high in the CPAP circuit, gases should be humidified to 100% and heated to a temperature of 37°C.

**Nasal interface (Fig. 8)** Continuous positive airway pressure is usually delivered to infants using nasal prongs or new generation nasal masks. Other interfaces which have been used are nasopharyngeal tubes, endotracheal tubes, pressurized plastic bags, head-box enclosures and tight-fitting face masks. In a systematic review assessing the efficacy of various interfaces for CPAP, short binasal prongs were found to be more effective than single prong in reducing the rate of reintubation. Furthermore, authors concluded that the improvement in respiratory parameters with short binasal prongs suggests they are more effective than nasopharyngeal CPAP in the treatment of early RDS. The short and wide binasal prongs also have the least resistance. Nasal injury is the commonest complication with nasal prongs. If the interface is not managed appropriately, serious erosions, perforations and disfigurement can occur. The incidence can be decreased by using appropriately fitting prongs, avoiding undue pressure on the nasal interface, properly supporting the CPAP tubing, keeping a distance of 2–3 mm between the nasal prong and nasal septum, applying lubrication, massage and skin protective dressings at contact points. Recently, two new interfaces have been introduced: (1) nasal mask; and (2) RAM's cannula. RAM's cannula consists of a binasal prong like the oxygen prongs and tubings but with a diameter much wider than conventional oxygen prong. This may be more comfortable for the infant and make nursing easier. New generation soft nasal masks have been shown to provide adequate nasal seal without increasing the injury. Alternating nasal mask with nasal prongs may minimize injury.

**Pressure-generating apparatus** Continuous positive airway pressure can be generated by the following devices:

- Expiratory flow valve (conventional ventilator) [ventilator-derived CPAP (VCPAP)]
- Underwater tube bubble CPAP (BCPAP)
- Variable flow CPAP [infant flow driver (IFD)]
- Heated humidified high-flow nasal cannulae (HHFNC)

Continuous positive airway pressure devices have traditionally been classified according to the pressure-generating apparatus and techniques used to control gas flow to the patient. There are two broad categories: (1) *constant flow devices*; and (2) *variable flow devices*. In *constant flow* devices, the flow is set by the clinician, and pressure is generated by controlling the resistance at the expiratory end of the tube. Conventional ventilators provide the simplest way to generate CPAP by controlling the expiratory valve

which generates PEEP. The advantage is that same machine can be used to provide mechanical ventilation. But ventilators are more expensive than stand-alone CPAP equipment. The most popular technique of generating CPAP is *bubble* CPAP. Devices which use fluidic control mechanisms to regulate the CPAP have been described as *variable flow devices*. Mechanisms within the CPAP pressure fluidic generator allow for additional gas delivery to the patient during inspiration in order to maintain a consistent airway pressure. During expiration also, the exhaled gases can escape through the additional tube, minimizing the work of breathing.

#### Bubble CPAP

The BCPAP system consists of a blended, humidified gas source (4–6 L/min) attached to nasal prongs by a length of inspiratory circuit. A separate length of expiratory circuit tubing is attached from the nasal interface, thus allowing egress of exhaled gases and system bias flow into a water seal column of sterile H<sub>2</sub>O/0.25% acetic acid mixture. The CPAP level is determined by the distance the distal end of the expiratory tubing is placed below the water seal surface (5 cm below surface = 5 cm H<sub>2</sub>O). But, the actual pressure delivered is flow-dependent with higher flow leading to higher CPAP pressure than the intended submerged length of tube.

The level of CPAP should be individualized to the baby's disease. As a general guideline, start CPAP of 5 cm H<sub>2</sub>O and FiO<sub>2</sub> of 0.5 to maintain normal pulse oximeter oxygen saturation (SpO<sub>2</sub>). Subsequent titration can be done based on the clinical improvement, blood gases and lung volume on chest radiograph. An orogastric tube (OGT) should be inserted to decompress the stomach. The signs of overinflation should be monitored—inadequate cardiac output (prolonged capillary filling time (CFT), reduced urine output, metabolic acidosis) and hyperinflated chest. Periodic inspection of the local area is important because patient interface can lead to septal and mucosal injury. CPAP is said to have failed when on a CPAP of 8–9 cm of H<sub>2</sub>O and FiO<sub>2</sub> of 60–70%, the infant has continuing desaturations, increased work of breathing, apnea or develops respiratory or metabolic acidosis.

#### Nasal Intermittent Positive Pressure Ventilation

Nasal intermittent positive pressure ventilation (NIPPV) has come up in the recent years as another alternative to CPAP or as a bridge between CPAP and mechanical ventilation. Apart from providing the PEEP, it also provides maximal inspiratory pressure at predetermined rates. Thus, it can be used in preterms who are not spontaneously breathing or who have failed maximal settings on CPAP. It has been seen that NIPPV has better success than CPAP in avoiding intubation when used as initial support and can avoid intubation in a significant proportion of those who fail CPAP. The main limitations relate to the amount of pressure that can be transmitted to the lungs because of several natural leaks and distension of stomach and intestines.

### Mechanical Ventilation

This used to be the mainstay of management of HMD. However, it was realized that it led to barotrauma, volutrauma, BPD and many other complications. Currently mechanical ventilation should be restricted for infants without any respiratory effort, those who have failed noninvasive modes of support or those with severe multisystem involvement. Even when it is used, the efforts should be to use it for minimum duration and extubate the infant at the earliest. The details of mechanical ventilation are discussed elsewhere. For best results with minimum damage, it is useful to follow the laws of ventilator efficiency (LOVE). These state that one needs to know the baby, the disease, the machine and have an EXIT strategy.

### Surfactant Replacement Therapy

Exogenous surfactant reduces the risk of mortality, air leaks and the combined outcome of BPD or death. Natural surfactants are

faster acting with lower incidence of pneumothorax and mortality as compared to first-generation artificial surfactant. As a result, the first-generation artificial surfactants are no longer available. Natural surfactants are derived from animal sources. Commonly available surfactant preparations in India are shown in **Table 1**. All commonly available brands are equally efficacious in similar doses. The difference lies in the volume to be administered because of different concentrations. Newer generation synthetic surfactants have been developed to alleviate the theoretical concerns of immunologic or infectious complications from animal-derived surfactant. These new products have synthetic peptides or proteins, such as KL4 in lucinactant, which mimics the actions of natural surfactant-associated proteins SP-B and SP-C. Lucinactant has been shown to be superior to older synthetic surfactants and is as efficacious as the animal-derived surfactants.

### Route of Administration

Surfactant is administered through the endotracheal tube either via side port (if present) or with help of a catheter inserted into the endotracheal tube. For infants on CPAP, the

**Figure 7** Components of continuous positive airway pressure  
Source: Professor Ashok K Deorari, AIIMS, New Delhi.

surfactant is administered by INSURE (INTubate, SURfactant and Extubate) technique. This involves intubation of the baby for the administration of surfactant and then extubating to CPAP within few minutes. The concept of INSURE is linked to the finding that a single dose of surfactant is enough if given early. Moreover, extubating the baby to CPAP further helps in keeping the lungs open. Since traditional method of surfactant instillation requires intubation, efforts have been made to find alternative methods of giving surfactant. Among such methods, which have been shown to be effective, are instillation via a feeding tube or vascular catheter inserted directly into the endotracheal tube. Lot of work is undergoing to produce an aerosolized form of surfactant and a device required for that so that even the insertion of feeding tube or vascular catheter into the endotracheal tube can be avoided.

### Timing of Surfactant

The practice has changed over the last decade. The earlier practice of giving prophylactic surfactant to extreme preterm neonates has been given up as intubation for instillation of surfactant even for short duration has been shown to initiate the inflammatory cascade leading to BPD and with very early application of CPAP, nearly half of the infants never require surfactant. Hence, the current practice is to give early rescue surfactant only if the infant requires intubation or the oxygen requirement persists to be more than 30–35% on adequate CPAP.

### Aftercare

Clinical care after surfactant administration is very important. Natural surfactant can dramatically improve the lung compliance within minutes. As a result, there is danger of overventilation and overoxygenation, which can lead to pneumothorax and oxygen toxicity. So, after surfactant administration, a close watch should be kept on pulse oximetry and  $\text{PaCO}_2$ . Similarly, tidal volumes (if baby is on ventilator) and chest movement should be closely monitored (pressures on the ventilator should be titrated accordingly). Volume-targeted ventilation is better than pressure-targeted ventilation in this scenario. As the lung compliance improves, the pressures automatically decrease in response to improving tidal volumes. This results in decreased barotrauma and air leaks.

### Supportive Therapy

The outcome of the infant is determined in a large part by the essential supportive monitoring and treatment directed towards all

**Figure 8** Various nasal interfaces used with continuous positive airway pressure

organ systems. An expert and efficient nursing care is very crucial for success of management.

**Thermoneutral environment** The neonate should be nursed in a thermoneutral environment. Hypothermia will initiate the cascade of pulmonary vasoconstriction and aggravate hypoxemia. Baby's temperature should be maintained between 36.5°C and 37.5°C. Very low birthweight neonates need incubator for maintenance of their temperature and for providing adequate humidity.

**Fluid and electrolyte balance** Fluids and normal acid-base balance should be maintained. Preterm babies have higher insensible water loss (40–100 mL/kg/day). Fluid intake should be titrated accurately by recording serial weight, intake/output, serum sodium and urine-specific gravity.

**Appropriate antibiotics** should be started in all cases of suspected sepsis or pneumonia. However, they should be stopped once the 48 hours blood culture is sterile and the infant does not have clinical features of sepsis, even if the infant continues to be on respiratory support.

**Calcium and glucose** homeostasis should be ensured.

**Maintain normal mean arterial pressure** Blood pressure and peripheral circulation should be monitored closely and nomograms used to define hypotension. Correct hypotension by using appropriate fluid volumes and inotropes if necessary.

**Hypovolemia and anemia** are to be treated adequately as necessary. Hematocrit should be maintained above 40% in the acute phase of the disease.

**Oral feeding** is withheld initially. Once the baby stabilizes on the respiratory support gavage feeding should be started and increased as per protocol and tolerance.

## PREVENTION

Prevention of prematurity seems to be most logical intervention to prevent HMD. Every effort should be done to prolong the pregnancy to at least 35 weeks. The decision to terminate pregnancy, in view of deteriorating maternal condition (e.g., uncontrolled hypertension) or fetal risk (e.g., reversed Doppler flows or chorioamnionitis), should be taken by the combined team of experts which includes obstetrician and neonatologist. Delivery should be conducted preferably in a center where there is facility for level III neonatal care, rather than transporting the baby after delivery (*transfer in utero*).

## Antenatal Steroids

Antenatal steroids are the cornerstone for the prevention of HMD. Treatment with antenatal steroids is associated with a significant reduction in neonatal death, HMD, intraventricular hemorrhage and necrotizing enterocolitis without increase in maternal risks. It is recommended that the treatment be used from 24 weeks to 34 weeks of gestation. Although the beneficial effects were found to be greatest if treatment was begun more than 24 hours before delivery, there is also a benefit if given for less than 24 hours. Hence, all women presenting with possible preterm labor between

24 weeks and 34 weeks should be administered a dose of antenatal steroid even if delivery is imminent and before referral.

Betamethasone is the preferred steroid as it leads to greater reduction in risk of death than dexamethasone and decreased risk of cystic periventricular leukomalacia (PVL) in the infant. Antenatal betamethasone is given in a dose of 12 mg intramuscular injection/dose, in two doses 24 hours apart. If betamethasone is not available, dexamethasone can be used in the dose of 6 mg per dose 12 hourly for four doses. It is identical in biologic activity to betamethasone. The beneficial effects of antenatal steroids start to wean off after 1 week of administration. Controversies exist regarding repeating the course of antenatal steroids in case baby is not delivered within a week. Repeated weekly courses of antenatal steroids result in modest improvements in incidence and severity of RDS, but there are serious concerns regarding smaller birthweight and head circumference. Hence, currently routine use of repeated doses of antenatal corticosteroids should be avoided. It is being explored whether a single dose can be repeated safely. It must be remembered that the cost of surfactant is considerably higher than antenatal steroids. Antenatal steroids provide more benefits on a wide range of organ systems and should be utilized more effectively.

## COMPLICATIONS

The complications may occur because of the disease itself but are mainly contributed by the treatments required.

### Respiratory

Pneumonia due to secondary acquired infections is the commonest complication. Air leaks are also common, though they have reduced in frequency in recent years due to better ventilators and ventilatory strategies. They include pulmonary interstitial emphysema, pneumothorax, pneumomediastinum and pneumopericardium. Inappropriate ventilation settings are the most common risk factors associated with air leaks. Hemorrhagic pulmonary edema (pulmonary hemorrhage) can be seen in extremely low birth babies. It is postulated that due to left ventricular failure and excessive shunting of blood from left to right across patent ductus arteriosus, there is rupture of pulmonary capillaries. Moreover, dramatic improvement in the lung compliance following surfactant therapy without concomitant decrease in ventilator settings may be contributory. It is manifested as pink frothy fluid in the endotracheal tube with simultaneous increase in ventilatory requirements on day 1 to 3 of life. BPD, the most dreaded complication is discussed elsewhere.

### Nonrespiratory Complications

Infants with HMD, especially those who are ventilated are prone to develop acquired sepsis, intraventricular hemorrhage, PVL, necrotizing enterocolitis and retinopathy of prematurity. They are also at risk for neurodevelopmental sequelae like cerebral palsy, vision and hearing defects, and developmental delay. These complications are mainly due to prematurity but can have an important contribution of the respiratory disease and the treatments used for it.

**Table 1** Surfactant preparations available in India

Brand	Source	Volume available and cost	Dosage recommended	Interval between doses	Maximum doses
Survanta (Abbott)	Bovine minced	8 mL (₹ 11,000) and 4 mL (₹ 6,000) vial	100 mg/kg = 4 mL/kg	6 hours	2
Curosurf (Nicholas/Abbott)	Porcine minced	1.5 mL (₹ 7,000) and 3 mL (₹ 13,000) vial	100 mg/kg = 1.25 mL/kg	12 hours	2
Neosurf (Cipla)	Bovine lavage	5mL (₹ 5,000), and 3 mL (₹ 3,000) vial	135 mg/kg = 5 mL/kg	12 hours	3

**IN A NUTSHELL**

1. Hyaline membrane disease is the most important cause of respiratory distress in preterm neonates. The incidence is inversely related to gestation.
2. The clinical features of HMD are related to surfactant deficiency and manifest as tachypnea, intercostal retractions and grunt.
3. Early CPAP support is the mainstay of treatment. It decreases the need for surfactant and mechanical ventilation. In extreme preterm infants, CPAP should be considered soon after birth in the delivery room.
4. Surfactant should be used as early rescue in infants who need intubation and those who continue to need more than 30–35% oxygen in spite of adequate CPAP support. If surfactant is required for an infant on CPAP, it should be given by INSURE technique or another minimally invasive method.
5. Intubation should be avoided as far as possible. NIPPV can help in many infants failing CPAP.
6. Infants with HMD needing respiratory support are at high risk of respiratory and nonrespiratory complications and sequelae.
7. Antenatal steroids are highly cost-effective in decreasing the incidence of HMD and its complications. They must be given to all women with threatened preterm delivery from 24 weeks to 34 weeks of gestation.

## Chapter 17.5

# Transient Tachypnea of the Newborn

Srinivas Murki

Transient tachypnea of newborn (TTN) is one of the most common causes of respiratory distress in the newborn. It is reported to occur in 0.6%, of term (gestation > 36 weeks) and 6.5% of late preterm (gestation 34–36 weeks) infants. Although most infants have an uneventful course, some may require respiratory support including continuous positive airway pressure (CPAP) or ventilation, prolonged oxygen supplementation and increased duration of hospital stay. Survival is almost universal in these infants. Recent data suggest an increased risk of wheezing episodes in infants or children with neonatal TTN.

## PATHOPHYSIOLOGY

During fetal life, fluid is secreted into the alveoli to maintain growth and function. Fetal lung volume approximates the functional residual capacity that is established after birth as the lung is aerated. Retained lung fluid immediately after birth precludes aeration of the alveoli, establishment of functional residual capacity and thereby a normal in utero to postnatal transition. Fluid fills the alveoli and moves into the interstitium that is eventually cleared by the lymphatics and blood vessels. This results in newborn developing respiratory distress immediately after birth. Possible reasons for the retention of lung fluid are as follows:

- *Delayed normal switch of the fetal chloride secretory channel* to postnatal sodium (ENaC) and water absorbing channel in the lung epithelium. Increased levels of catecholamine and other hormones in late gestation promote the switching of the chloride secreting channel to sodium absorbing channel. Increased postnatal oxygen tension augments the gene expression and function ability of the ENaC channel. Antenatal glucocorticoids augment the expression of ENaC channel.
- *Delayed passive absorption of lung fluid* Oncotic pressure differences between the alveoli, interstitium and blood vessels promote passive absorption of the lung fluid. This absorption occurs along the aquaporin-5 water channels. There is an increased expression of these channels after birth in newborns with TTN.
- *Vaginal squeeze* The vaginal squeeze during labor contributes to a small fraction of the extrusion of the lung fluid at birth.
- *Inadequate surfactant function* Infants with TTN in comparison with those without TTN have lesser surfactant function as evidenced by lower lamellar body count in their gastric aspirates.

## RISK FACTORS

- *Late preterm infants* Lower the gestation, higher is the risk. Infants born at 34 weeks are at higher risk of developing TTN than those born at 37 weeks.
- *Infant of diabetic mother* TTN is more common in these infants secondary to delayed fluid absorption and higher incidence of cesarean delivery.
- *Male infant* Testosterone may affect the expression and function of the ENaC channel in the alveolar epithelium.
- *Cesarean section* Although in comparison with vaginal delivery, incidence and severity of TTN is more in cesarean section, TTN is more common if the cesarean section occurs before onset of labor than otherwise.

- Infants who are *growth restricted* or large for gestation
- *Maternal asthma*

## CLINICAL FEATURES

Infants with TTN present with respiratory distress immediately after birth or within the first 6 hours of life. In many, the severity of distress improves with time. Tachypnea (respiratory rate > 60/min), normal or increased chest expansion, mild or moderate chest recessions, nasal flaring, grunting, occasional crepitation and increased oxygen requirement are the classical clinical signs. Saturations improve with oxygen supplementation and rarely infants may require CPAP or ventilation to improve oxygenation and reduce the work of breathing. The distress is usually passive by 24 hours and in some it may persist till 72 hours of life. Resolution of grunting and chest recessions precedes the normalization of respiratory rate.

## DIAGNOSIS

### Chest Skiagram

There may be evidence of hyperinflation and may also be of normal volume in some cases. The perihilar vascular markings may be prominent (which is probably due to lymphatic engorgement) and there may be evidence of fluid in the fissures (**Fig. 1**). Occasionally there may be associated cardiomegaly. The chest radiograph usually clears by 3–7 days.

**Figure 1** Prominent perihilar markings, fluid in the horizontal fissure and cardiomegaly in a newborn with transient tachypnea of newborn

## Differential Diagnosis

Respiratory distress syndrome, pneumonia, asphyxial lung injury, pneumothorax and congenital heart disease are the common conditions that would need to be differentiated from TTN.

### Pneumonia

Onset of respiratory distress may be immediately after birth or later in the first 24 hours of life. Maternal fever, foul-smelling liquor, maternal urinary tract infections, prolonged rupture of membranes, prolonged duration of labor and mother on antibiotics are the usually recognized antecedent risk factors. Chest X-ray may show infiltrates in one or more zones of lung.

### Congenital Heart Disease

Persistent pulmonary hypertension, obstructive lesions such as critical aorta stenosis and obstructed total anomalous pulmonary

venous connection may present as respiratory distress with onset from birth. High oxygen requirement, oxygen liability, normal lung fields and cardiomegaly are features suggestive of pulmonary hypertension. Low volume pulses, murmurs, cardiomegaly and good volume lungs or congested lungs are features suggestive of congenital heart disease.

### Respiratory Distress Syndrome

Preterm or late preterm infant, onset of respiratory distress at birth with progressive worsening, and radiological findings of small volume lungs, reticulogranularity and air bronchograms, differentiates respiratory distress syndrome (or hyaline membrane disease) from TTN.

### Pneumothorax

Early onset of respiratory distress with progressive worsening, differential air entry on auscultation of chest, positive transillumination test and chest X-ray are useful in differentiating pneumothorax from TTN.

## MANAGEMENT

Management is mostly supportive. Maintaining thermoneutral environment, intravenous fluids, early nutrition and oxygen supplementation form the mainstay of therapy. There is no role of antibiotics in TTN unless pneumonia or sepsis is suspected.

### Respiratory Support

All infants with respiratory distress should be connected to a pulse oximeter and severity of distress monitored with Downe's score or Silverman Anderson score. Oxygen is administered to maintain saturations between 90% and 95%. Fractional inspired oxygen concentration ( $\text{FiO}_2$ ) needs to be monitored and tailored to maintain oxygenation in the acceptable range of 90–95%. Supplemental oxygen should be provided only as long as the infant needs it and one should avoid excess and prolonged oxygen therapy. Infants with progressively worsening respiratory distress and increased oxygen requirement need to be supported with nasal continuous positive airway pressure. CPAP is indicated if the Silverman score more than 5 or Downe's score is more than 5 and/or  $\text{FiO}_2$  requirement is more than 0.60. Those with persisting or progressive respiratory distress should be screened for infections (pneumonia or early onset sepsis) and congenital heart disease (by 2-D echocardiography).

Infants delivered in facilities without respiratory support care such as CPAP or mechanical ventilation should be referred to tertiary care neonatal units if there is persistent and worsening respiratory distress at 6 hours of life, or radiological findings not consistent with TTN on the chest X-ray.

### Fluids and Feeding

There is no evidence that fluid restriction or diuretic therapy alters the course of disease. Most of these infants would not be able to

suck on the breast due to their respiratory distress, and, therefore, would need to be provided intravenous dextrose in the initial few hours or during the first day of life. Some of these infants who cannot feed on their own but have mild-moderate respiratory distress could be fed expressed breastmilk by orogastric tube.

## PREVENTION

Antenatal steroids given to mothers with elective cesarean section before 37 weeks of gestation may reduce the incidence and severity of respiratory distress in late preterm infants. However, this should not be a routine practice unless more evidence is available. When termination of pregnancy is elective, it preferably should occur at or after 39 weeks of gestation.

### IN A NUTSHELL

1. Transient tachypnea of newborn is the most common cause of respiratory distress in term and late preterm infants.
2. Retained lung fluid leads to lower functional residual capacity, which in turn results in hypoxia and increased work of breathing.
3. Late preterm birth, maternal diabetes, elective cesarean are the main risk factors for TTN.
4. Tachypnea, chest recessions, grunting with onset of respiratory distress within the first few hours of birth with gradual and spontaneous resolution differentiates TTN from other disorders with respiratory distress in the newborn.
5. Persistent respiratory distress with increased oxygen requirement should alert the clinician to rule out early onset sepsis and congenital cardiac diseases.

## Chapter 17.6

# Meconium Aspiration Syndrome

Naveen Jain

Meconium (desquamated intestinal epithelium, skin, lanugo hair, amniotic fluid) may be passed into the amniotic fluid before or during delivery of baby in some pregnancies. Meconium aspiration syndrome (MAS) refers to a syndrome of respiratory stress that occurs in some of these babies (mostly term/post-term) born through meconium-stained amniotic fluid (MSAF). A fraction of babies with MAS can progress to severe hypoxemic respiratory failure.

## EPIDEMIOLOGY

Reported incidence of MSAF is about 10% of all pregnancies. The incidence has decreased a little in the last decade due to improved fetal monitoring and timely termination of pregnancy. About 5% of babies born through MSAF develop respiratory distress due to MAS.

## ETIOLOGY

Meconium-stained amniotic fluid is more common in post-term pregnancy; however, current obstetric practices seem not to allow pregnancies to go beyond term gestation. It can also be seen in growth-retarded fetuses, which experience placental insufficiency. Breech presentation is associated with passage of meconium during labor. Meconium passage may be a sign of fetal stress. Fetal hypoxia and acidosis can increase gut motility (higher levels of hormone motilin demonstrated) of fetus. Rarely, it is reported to be a sign of fetal diarrhea when there is fetal infection with listeriosis.

## PATHOPHYSIOLOGY

Although *aspiration* of meconium and associated chemical pneumonitis, surfactant inactivation, airleaks and collapses due to mechanical obstruction are apparent direct causes of respiratory distress, persistent pulmonary hypertension (MAS-PPHN) is the determinant of severity. When perinatal asphyxia is the cause of MAS, multi-organ dysfunction due to hypoxia, ischemia worsens the outcome. On some occasions, secondary bacterial infection may complicate the course.

## CLINICAL FEATURES

The diagnosis is essentially clinical-respiratory distress at birth or within hours in setting of MSAF. Investigations are only necessary to manage the respiratory and multisystem symptoms. Most recommend is close observation for respiratory distress for at least 6 hours, if baby is delivered through MSAF.

Meconium staining of umbilical cord/nail points to MSAF when the information is not available in noninstitutional birth. If the baby was depressed and intubated, finding meconium on endotracheal suction is evidence of MAS.

Babies with MAS may have two dominant patterns of lung involvement. In the more common presentation, the lungs are nonhomogeneously atelectatic (patchy shadows) (**Fig. 1**) or overinflated due to meconium plugs and ball valve effect respectively. Such babies have a splinted and prominent chest wall. In some babies, surfactant inactivation is the dominating pathology; these babies behave like respiratory distress syndrome (RDS) with tachypnea, retractions and oxygen need. X-ray chest can be typical *white out* like in RDS. In babies with RDS-like picture, surfactant therapy may be beneficial.

**Figure 1** Coarse nodular opacities in a neonate with meconium aspiration syndrome (MAS)

Tachypnea is common in MAS and can last for 2–3 weeks in some babies even after clinical improvement. Chest X-ray and arterial blood gas will help optimize respiratory care. Oxygenation indices calculated from  $\text{PaO}_2$ ,  $\text{FiO}_2$  and mean airway pressure (MAP) can objectively guide scaling therapies to high frequency ventilation, use of inhaled nitric oxide and extracorporeal membrane oxygenation (ECMO) in babies with severe hypoxemic respiratory failure.

Blood cultures must be taken before starting antibiotics in symptomatic baby/baby with X-ray changes. As meconium is *sterile* and inflammatory markers like C-reactive protein (CRP) and complete blood count (CBC) may be false positive, clear decision on discontinuing antibiotics is difficult.

## DIFFERENTIAL DIAGNOSIS

Respiratory distress in newborn, born through MSAF may be manifestation of infection (congenital pneumonia), fetal hypoxia (PPHN, pulmonary infarct/hemorrhage). MSAF may be an incidental event in babies with congenital malformations like congenital diaphragmatic hernia or other malformations causing respiratory distress in a term born neonate and only an antenatal sonography or postnatal X-ray may point to primary disease.

1. *Transient tachypnea of newborn* Some of the babies born through MSAF may settle down in hours and have no typical X-ray changes.
2. *Early onset sepsis/congenital pneumonia* The commonest cause of respiratory distress in term born babies is infection. The stress of infection may cause the fetus to pass meconium in utero. The diagnosis of infection must be excluded with surety by cultures and negative inflammatory markers to safely stop antibiotics.
3. *Asphyxial lung injury* Fetal distress, asphyxia and meconium staining of liquor and aspiration are overlapping clinical situations. Asphyxia can cause lung injury due to infarct, hemorrhage, protein leaks and surfactant insufficiency and

present the same as MAS. It may not be clinically possible to distinguish or confirm even by labs. Physiology directed therapy is preferred to pointing to pathological babies of respiratory distress/failure.

4. **Congenital malformations** Like congenital diaphragmatic hernia, unlike in preterm babies, where RDS (respiratory distress due to surfactant insufficiency) outnumbers all other causes, in term born babies, congenital malformation is an important cause especially if there is no infection or asphyxia setting. An X-ray must be done in all term born babies with respiratory distress.

## COMPLICATIONS

Neonates with MAS usually also have hypoxic-ischemic encephalopathy (HIE) as a comorbidity. But in addition, MAS itself can be associated with several other complications; major ones include airleaks (**Fig. 2**), PPHN and infection.

**Pulmonary airleaks** It is one of the most frequent complications and has been reported in up to 15% of neonates with MAS who are not mechanically ventilated. In mechanically ventilated neonates with MAS, this could be as high as 50%. Pneumothorax may be unilateral or bilateral and can result in rapid deterioration in the baby's condition. The incidence of airleaks with MAS has decreased with improved ventilators, ventilation techniques with shorter inspiratory time, possibly better synchronization, use of surfactant and less aggressive ventilation with support of high frequency and nitric oxide. Intercostals drainage may be required if X-ray confirms a pneumothorax.

**Persistent pulmonary hypertension (PPHN)** The incidence varies and reported to be as high as 40%.

**Infection** This is a complication seen more often with ventilated neonates.

## MANAGEMENT

### Initial Management

The severity of respiratory distress may be underestimated in term babies. It is, therefore, important to observe and monitor all infants

born through MSAF for hypoxia or respiratory distress for at least 6 hours.

**Minimal handling** These babies must be minimally handled because they run the risk of going into severe hypoxia when agitated.

**Thermal environment** This must be maintained in a thermoneutral environment.

**Glucose and fluids** It is important that these babies are provided intravenous fluid as symptomatic babies would feed poorly and may become hypoglycemic. It is important that blood sugars are monitored to maintain euglycemia.

## Respiratory Support

### Oxygen Therapy

Most babies when noted to be hypoxic can be managed by providing supplemental oxygen therapy by a headbox. Some of these babies may need  $\text{FiO}_2$  of over 60% for several days. Those babies who need rapid increase in oxygen concentration to maintain  $\text{SaO}_2$  are candidates for mechanical ventilation.

### Acid-base Homeostasis

It is important to maintain acid-base homeostasis. Severe metabolic acidosis may precipitate PPHN and, therefore, may need alkali therapy. Evidence of respiratory failure (raised  $\text{paCO}_2$ ) is an indication for mechanical ventilation.

### Ventilation

Respiratory distress can vary in severity—in some cases, only tachypnea and mild hypoxia requiring oxygen by hood may settle in few days. In at least 30% babies, severe respiratory distress may require ventilation. If babies have severe respiratory distress requiring high ventilator pressures or air leaks with high  $\text{PaCO}_2$ , high frequency ventilation may be used. If there is coexisting PPHN causing severe hypoxia confirmed by echocardiography, inhaled nitric oxide may be required.

### Surfactant

If baby is on high respiratory support and X-ray is RDS-like, surfactant therapy may be considered. Meta-analysis of four trials enrolling 326 infants showed no effect on mortality. The risk of requiring ECMO was significantly reduced in a meta-analysis of two trials ( $n = 208$ ); (typical relative risk 0.64, 95% CI:0.46, 0.91; typical risk difference -0.17, 95% CI:-0.30,-0.04); number needed to treat to benefit 6 (95% CI:3, 25). One trial ( $n = 40$ ) reported a statistically significant reduction in the length of hospital stay [mean difference—8 days (95% CI:14, 3 days)]. There were no reductions in duration of assisted ventilation, duration of supplemental oxygen, pneumothorax, pulmonary interstitial emphysema, air leaks, chronic lung disease and need for oxygen at discharge. Studies have described the use of higher doses of surfactant than for RDS, surfactant lavage with variable short-term benefits. In infants with MAS, lung lavage with diluted surfactant may be beneficial. Meta-analysis of two studies did not show a decrease in mortality or the use of ECMO. For the composite outcome of death or use of ECMO, a significant effect favored the lavage group (typical relative risk 0.33, 95% CI:0.11 to 0.96; typical risk difference -0.19, 95% CI:0.34 to -0.03; number needed to benefit (NNTB)).

### Steroids

In published trials, no benefits of steroid therapy in the management of MAS were demonstrated.

## OUTCOME

In babies with MAS, comorbidities like PPHN, asphyxia, bacterial pneumonia and airleaks determine the risk of progressive

**Figure 2** Unilateral pneumothorax in a neonate with MAS

respiratory failure and multiorgan injury. Mortality in MAS-PPHN is much higher than babies ventilated for RDS/pneumonia. Need for higher device support like high frequency and iNO must guide early referral.

## PREVENTION

Fetal monitoring, avoiding post-term deliveries have decreased the incidence of MAS. It is not proven whether therapies like amnioinfusion have influence on incidence or severity of MAS.

### IN A NUTSHELL

1. MAS is seen mostly in post-term neonates or those with placental insufficiency
2. All babies born through MSAF must be monitored for at least 6 hours for respiratory distress
3. Persistent pulmonary hypertension and airleaks are common complications in babies with MAS
4. High-frequency ventilation and inhaled nitric oxide may be beneficial in severe hypoxic respiratory failure.

## Chapter 17.7

# Pulmonary Air Leaks in the Newborn

Manish Balde, Sanjay Wazir

Pulmonary air leaks are most frequent in the newborn period than any other time in life. These are a result of overdistension of alveoli causing tissue rupture at the alveolar bases and leakage of air into the extra-alveolar spaces where it is not normally present. The resulting disorders depend upon the location of the air and ease with which the gas can move. The most common conditions are pneumothorax, pneumomediastinum, pulmonary interstitial emphysema and pneumopericardium. Rarer forms are pneumoperitoneum and subcutaneous emphysema.

### INCIDENCE

One percent of babies develop spontaneous pneumothorax at birth. Mostly are unilateral with right side more frequently involved than the left side. The incidence depends upon the factors including birthweight, the presence of lung disease and the method of detection. The incidence is increased in preterm infants, who often have pulmonary disease. In a report from the Vermont Oxford database, pneumothorax was reported in 6.3% of 26,007 infants with birthweight 500–1500 g in 1999. In India, in a recent study from Manipal Hospital, there were equal number of term and preterm babies with pneumothorax and incidentally only half of those were related to ventilation. The reported mortality is about 40%, and most of the cases are present in the first 48 hours.

### PNEUMOTHORAX

This condition results in collection of air between the visceral and parietal pleura and significant accumulation of air results in collapse of the lung (Fig. 1).

### Etiology

#### Spontaneous

Most cases are present early. The most common causes are:

- High transpulmonary pressures generated in the first few breaths.

Figure 1 Right-sided pneumothorax with collapsed lung

- Rupture of a congenital bulla.
- Familial spontaneous pneumothorax—runs in the families, but mode of inheritance is not very clear, rare entity.

### Pulmonary Disorders

Pneumothorax is common in meconium aspiration syndrome (MAS) (10–30%), pulmonary hypoplasia and severe hyaline membrane disease requiring significant peak inspiratory pressures during mechanical ventilation.

### Direct Injury

By a suction catheter advanced into the right main bronchus and has also been associated with central venous catheter placement.

### Surfactant

Synthetic surfactants, although no longer used now, but were associated with increased incidence of air leaks than natural surfactants. In a recent large retrospective study from the Pediatrix database of 51,282 preterm infants (median gestational age 30 weeks), who received surfactant therapy between 2005 and 2010, there were no significant differences amongst the three natural preparations after adjusted analysis in the outcomes of air leak syndromes.

### Inspired Gas Temperature

Maintaining the temperature of the inspired gases in very low birth weight (VLBW) babies to more than 36.5°C, resulted in 70% reduction in the rate of pneumothorax, probably because of improved clearance of secretions at higher temperature and humidity.

### Ventilatory Strategies

High mean airway pressure (MAP) especially more than 12, high positive end-expiratory pressure (PEEP), Long inspiratory time (> 0.5 sec) and inspiratory time longer than expiratory time (I:E ratio) more than 1:1 is associated with higher risk of air leaks. Volume ventilation has been shown, in a recent meta-analysis, to have reduced rates of air leaks than the pressure controlled mode and also regular monitoring of tidal volumes on the graphics section of the ventilator results in lesser air leaks.

### Muscle Relaxants

For ventilated preterm infants with evidence of asynchronous respiratory efforts, neuromuscular paralysis with pancuronium seems to result in a trend toward lesser air leaks. The routine use of pancuronium or any other neuromuscular blocking agent in ventilated newborn infants cannot be recommended based on current evidence and lack of data on long-term neurological and pulmonary outcomes. Similarly, the routine use of opioids in mechanically ventilated babies is not recommended at present.

### Modes of Ventilation

- *High-frequency positive pressure ventilation (HFPPV)* Although the impact of breath rates upward of 80 per minute has not been systematically compared to lower rates, but ventilating at 60/min as compared to 30–40/min has resulted in approximately 30% reduction in the frequency of air leaks. However, the impact of these studies in the current era may be difficult to apply as these studies were done in an era where antenatal steroids and postnatal surfactant usage was not very common.
- *Patient-triggered ventilation (PTV)* If the baby's attempts to breathe are synchronized with the mechanical breaths from the ventilator, less pressure may be needed. This could reduce the chance of air leak. A meta-analysis of six studies however has shown no benefit of PTV in prevention of air leaks. The results

of this meta-analysis might have been skewed because of the study of Baumer et al. where more than 900 babies showed an increased incidence of air leaks with PTV. The babies in this trial were supported by a ventilator which used an airway pressure trigger. In very premature babies, airway pressure trigger has a long trigger delay which results in inflation extending into the active expiration and higher rate of asynchrony. This data would have to be looked at again in light of better sensing devices, incorporation of flow triggers rather than pressure triggers and use of termination sensitivities in the current ventilators.

- **High-frequency ventilation** Both high-frequency oscillatory ventilation (HFOV) and high-frequency jet ventilation (HFJV) can provide adequate gas exchange using extremely low tidal volume and supraphysiologic rate in neonates with acute pulmonary dysfunction, and they are considered to have the potential to reduce the risks of air leak syndrome in neonates. However, there is still no conclusive evidence that HFOV or HFJV can help to reduce new air leaks in published neonatal clinical trials.

### Clinical Features

There are three kinds of presentation of a pneumothorax:

1. **Asymptomatic** Small pneumothorax can be completely asymptomatic and picked up only on a routine chest X-ray.
2. **Respiratory deterioration** Sudden worsening of the respiratory status in a neonate who was stable otherwise or on ventilator.
3. **Signs of cardiovascular compromise** In case of large tension pneumothorax (**Fig. 2**), there is initial tachycardia followed by bradycardia, narrowing of pulse pressure and hypotension and decreased capillary refill time.

The findings could include asymmetrical chest with prominence on the affected side, decreased breath sounds on the affected side, shift of the point of maximal cardiac impulse away from the affected side and distant heart sounds. Cyanotic upper half with paler lower half can be seen in case of tension pneumothorax. An early sign may be a sudden decrease of voltage of the QRS complex on the oscilloscopic cardiac tracing.

### Diagnosis

#### Blood Gas

Hypoxemia and marked hypercarbia with resultant respiratory acidosis.

#### Transillumination

Transillumination of the chest with high intensity fiberoptic probe in a darkened room may help make the diagnosis. When the

fiberoptic probe is placed along the posterior axillary line on the side, the whole chest *lightens up* on the side of the pneumothorax (**Fig. 3**). This however could be unreliable in extremely premature babies because of the small chest, term babies with chest wall edema, severe subcutaneous emphysema in a premature infant with **pulmonary interstitial emphysema (PIE)**.

### Chest Radiograph

**Anteroposterior view** Findings include (i) shift of the mediastinum away from the pneumothorax; (ii) depression of diaphragm on the side of the pneumothorax; (iii) affected side appears hyperlucent; and (iv) air in the pleural space outlining the visceral pleura with collapse of lung on that side.

**Lateral decubitus view** A very small pneumothorax may only be appreciated in lateral decubitus view with the affected side up.

**Ultrasound of the chest** The absence of lung sliding (seashore sign), stratosphere sign and comet tails confirm the presence of pneumothorax.

### Differential Diagnosis

Other air leaks like pneumomediastinum, congenital diaphragmatic hernia, congenital lobar emphysema, congenital cystic adenomatoid malformation and pulmonary cysts.

### Management

#### Asymptomatic Pneumothorax

Infants without a continuous air leak or respiratory distress and who have no underlying lung disease or have no need for assisted ventilation may be observed closely without specific treatment. The pneumothorax will typically resolve in one to two days.

#### Oxygen Treatment

Animal studies have shown that the use of higher inspired oxygen concentration up to 50% may hasten the resolution of small pneumothorax. This intervention is, however, not recommended because of risk of hyperoxia, especially in a preterm infant. Oxygen therapy should be tailored based on oxygen saturation targets.

#### Conservative Management in Ventilated Babies

In mechanically ventilated infants, ventilator settings should be adjusted to minimize MAP by reducing peak inspiratory pressure, PEEP and inspiratory duration. In some cases of infants who do not

**Figure 2** Right-sided tension pneumothorax

**Figure 3** Transillumination of chest in pneumothorax

require high ventilatory settings, spontaneous resolution may occur without chest tube placement. In a retrospective study from Israel, which included 136 VLBW babies, 101 babies (74%) were treated initially with a chest tube and 35 babies (26%) without a chest tube. Of those who did not receive a chest tube initially, 14 were treated with needle aspiration and 21 with expectant treatment.

### Thoracocentesis

This is an emergency treatment for symptomatic pneumothorax. It may be the only intervention required in an infant who is not mechanically ventilated and may be a temporary measure in an infant who is mechanically ventilated. The site of puncture should be at the second intercostal space along the midclavicular line on the suspected side.

### Chest Tube Placement

For definitive drainage in tension pneumothorax or in case of significant deterioration in a mechanically ventilated baby, insertion of a chest tube is necessary. The position of the chest tube and resolution of the pneumothorax should be confirmed by chest radiography. Negative suction applied to the drainage bottle can help evacuate air in cases of large pneumothoraces (Fig. 4).

### Recalcitrant Pneumothorax

This is a difficult situation and some suggested therapies could be:

- High-frequency ventilation using a low volume strategy to lower the MAP, although the evidence for this is not very strong.
- Unilateral lung intubation for duration of 48 hours may be tried.
- Fibrin glue such as cryoseal C has been injected in the chest tube with marked reduction in the air leak, although this therapy is associated with significant adverse effects.
- Occlusion of the right main bronchus with a Fogarty catheter produced rapid improvement in a 26 weeks gestation infant who had a nonresolving pneumothorax.

## PULMONARY INTERSTITIAL EMPHYSEMA (PIE)

It consists of air trapped in the perivascular tissues of the lung from the alveolar over distension.

### Incidence

*Pulmonary interstitial emphysema* was believed to occur exclusively in the VLBW infants on ventilatory support in the first 48–72 hours of life. However, there have been case reports of PIE in late preterms on continuous positive airway pressure (CPAP) and in term infants.

**Figure 4** Three-bottle technique for pneumothorax drainage

## Pathophysiology

Pulmonary interstitial emphysema may precede the development of pneumothorax or other air leaks. It results from the dissection of air into the perivascular tissue of the lung due to rupture of the over distended alveoli. This interstitial air moves in the connective tissue plane and around the vascular axis. Minimising pulmonary over distension should reduce the risk of PIE. The condition could be unilateral or bilateral.

## Clinical Features

It usually presents within first few days of life with gradually worsening of hypercarbia and hypoxemia. Increase in ventilatory settings does not improve the hypercarbia. Over distension of the lung may cause vascular compression, resulting in decreased venous return and impaired cardiac output.

## Diagnosis

On a chest X-ray, interstitial air can appear as either cyst-like (Fig. 5) or linear radiolucencies (Fig. 6). The former are approximately 1–4 mm in size. The linear radiolucencies are coarse, nonbranching, streaks that are seen in both the peripheral and medial lung fields. Transillumination of the chest would produce picture similar to the large pneumothorax.

**Figure 5** Pulmonary interstitial emphysema (multiple small cysts in both the lung fields; more prominent on the right side)

**Figure 6** Pulmonary interstitial emphysema (Linear hyperlucent streaks in upper left lobe)

## Differential Diagnosis

The chest X-ray can be confused with lobar emphysema or if more localised with cystic adenomatoid malformation of the lung. Linear translucencies can be confused with air bronchograms in a severe respiratory distress syndrome (RDS), but in that case, the translucencies do not extend toward the periphery of the lung.

## Management

### Generalized PIE

- Sedation/analgesia** In a neonate who is having obvious asynchrony on the ventilator, we would need to sedate or use opioids to reduce the risk of extension of PIE to pneumothorax.
- Ventilatory management** Decreasing the MAP as much as possible is a goal. This can be achieved by reducing the peak inspiratory pressure, PEEP or inspiratory duration. The inspired oxygen concentration should be increased to compensate for the decreased MAP. High-frequency ventilation is often utilized in this scenario, but there is no sufficient conclusive evidence of its benefit.

### Localized PIE

- Shorter inspiratory times** This has been used to direct the delivered volume preferentially toward units of the lung with relatively normal time constants, while avoiding inflation of longer time-constant emphysematous areas. However, because of limited volume delivery with such a manoeuvre, this is likely not to be tolerated for long.
- Selective intubation of contralateral lung** Intubation of the right main bronchus is easy because of anatomical reasons and can be achieved by just intubating a little deeper. Intubation of the left main bronchus is facilitated by positioning the bevel on the end of the endotracheal tube so that the long part of the tube is directed toward the main bronchus to be intubated. Turning the infant's head to the right moves the tip of the endotracheal tube to the contralateral side of the trachea and thus the left main bronchus is intubated. Cutting a hole in the tube reduces the risk of upper lobe collapse. Duration of this should be 48 hours, although it can be extended up to 5 days in case of nonresolution. Similar results can be achieved by blocking the right main bronchus with a fogarty catheter.
- Lateral decubitus position** In such a position, the uppermost lung receives the greater proportion of the ventilation; hence, by underventilation, decompression of the dependent lung is encouraged.

**Figure 7** Pneumomediastinum

## PNEUMOMEDIASTINUM

This is a condition consisting of air in the mediastinal space.

### Clinical Features

Most cases of pneumomediastinum are asymptomatic. Large collections of air may result in tachypnea and cyanosis. Pneumomediastinum is usually suspected on the routine newborn examination when the heart sounds are distant.

### Diagnosis

The diagnosis is made on a chest radiograph. If the amount of air is large, the pneumomediastinum can usually be appreciated on an anteroposterior view as a halo of air around the lateral border of heart (**Fig. 7**) or on a lateral view as a retrosternal or superior mediastinal radiolucency (**Fig. 8**). It is most reliably seen on a left anterior oblique view, in which even minimal air in the mediastinum surrounds the thymus and lifts it from the cardiac shadow, resulting in the characteristic *spinnaker sail* sign (**Fig. 9**).

### Management

Pneumomediastinum usually resolves spontaneously, and requires no specific treatment. The patient should be observed

**Figure 8** Pneumomediastinum lateral chest X-ray (showing air behind the sternum)

**Figure 9** Pneumomediastinum (Spinnaker Sail Sign)

closely for evidence of cardiorespiratory compromise and development of other air leaks, especially pneumothorax. Drainage is recommended for rare cases of tension pneumomediastinum, causing cardiovascular compromise. Attempts, however, at draining mediastinal air are often unsuccessful despite needling or tube drainage and indeed may cause complications, such as phrenic nerve damage. If the infant requires ongoing ventilatory support, use of a lower airway MAP should be attempted.

## PNEUMOPERICARDIUM

This condition is characterized by air in the pericardial space, which could potentially result in cardiac tamponade.

### Etiology

- Spontaneous
- Associated with ventilation in preterm babies
- Congenital absence of left pericardium—either partial or complete—is a rare condition. The complete absence is usually asymptomatic throughout life. Radiographic findings of complete absence of the left pericardium include an unusual cardiac silhouette with elongation of the left heart border, leftward shift and clockwise rotation of the heart, a radiolucent cleft between the ascending aorta and the main pulmonary artery and lucency separating the heart and the left hemidiaphragm. The first two findings related to the abnormal mobility of the heart, the later two result from interposition of lung that is normally restricted by the left pericardium.

### Clinical Features

The typical presentation is the abrupt onset of hemodynamic compromise due to cardiac tamponade. Acute collapse may be preceded by tachycardia and a narrowed pulse pressure. Findings on physical examination include bradycardia, hypotension, increased respiratory distress and cyanosis. The heart sounds may be muffled or distant. Some infants have a pericardial knock or a characteristic mill wheel-like murmur. The electrocardiogram may show low voltages with a small QRS complex.

### Diagnosis

Gas can be seen completely surrounding the heart, outlining the base of the great vessels and contained within the pericardium (**Fig. 10**). Gas does not rise above the upper border of the pericardium, whereas with a pneumomediastinum air is seen anterior to the heart with hyperlucency behind the sternum. Air is seen inferior to the diaphragmatic surface of the heart and this also differentiates this abnormality from a pneumomediastinum. Air behind the heart is virtually diagnostic of a pneumopericardium.

### Management

If it is completely asymptomatic, then they should be left alone with a little oxygen to maintain saturation in the target range of 90–95%. If the baby has features of cardiovascular compromise, it is better to do a needle aspiration by pericardiocentesis.

## OTHER AIR LEAKS

Pneumoperitoneum and subcutaneous emphysema are uncommon types of air leak. Pneumoperitoneum may occur when extrapulmonary air decompresses into the peritoneal cavity. The diagnosis is made on an abdominal radiograph and usually has little clinical significance. However, it must be differentiated from intraperitoneal air due to a perforated viscus.

Subcutaneous emphysema typically occurs in the face, neck or supraclavicular region. It typically presents as crepitus detected by palpation. It usually has no clinical significance, although large air collections in the neck may cause tracheal compromise.

### IN A NUTSHELL

- Air leaks are not uncommon causes of neonatal respiratory distress.
- A common cause is assisted ventilation; they can also occur spontaneously.
- Air can accumulate in the pleura (pneumothorax), in the lung interstitium (pulmonary interstitial emphysema), in the mediastinum or pericardium.
- In ventilated neonates with sudden cardiovascular compromise, pulmonary air leaks must always be suspected.
- Transillumination at the bedside is a useful diagnostic aid for pulmonary air leaks in the newborn.
- Pulmonary air leaks can rarely present as pneumoperitoneum.

## Chapter 17.8

# Persistent Pulmonary Hypertension (PPHN)

Neeraj Gupta

Persistent pulmonary hypertension of the newborn (PPHN) is a disease which is characterized by failure to achieve or sustain the normal decrease in pulmonary vascular resistance (PVR) at birth. Elevated PVR results in extrapulmonary shunting of deoxygenated blood via fetal channels (ductus arteriosus and foramen ovale) to systemic circulation resulting in hypoxemic respiratory failure and multi-organ dysfunction. PPHN is a serious disease with significant morbidity and mortality and is primarily restricted to term and post-term infants. Recently, it has also been described in preterm infants with bronchopulmonary dysplasia (BPD). Advent of inhaled nitric oxide (iNO), along with better understanding of disease at molecular level has revolutionized its management over last one decade.

## NORMAL FETAL CIRCULATION AND TRANSITION AT BIRTH

Placenta, but not the lungs, serves as the organ of gas exchange inside the fetus. High PVR during fetal life actually helps in gas exchange by diverting most of the right ventricular output through ductus arteriosus to the descending aorta and to the placenta circulation. Blood returning from the placenta is rich in oxygen and is directed from the right atrium through the foramen ovale into the left atrium, whereas that from the brain and heart having low oxygen content is directed from the right atrium into the right ventricle. Only 10–20% of the combined ventricular output is directed to pulmonary vascular bed in the human fetus.

Mechanical compression of small pulmonary arterioles by fluid-filled alveoli, low arterial oxygen levels, elevated levels of pulmonary vasoconstrictors [endothelin-1 (ET-1), leukotrienes and thromboxane] and relative lack of vasodilators [nitric oxide (NO) and prostacyclin (PGI<sub>2</sub>)] maintains high PVR during fetal period. PVR increases with increasing gestational age despite the increasing surface area of pulmonary vascular bed suggesting active pulmonary vasoconstriction during late gestation. ET-1 is a potent vasoconstrictor and is synthesized by pulmonary vascular endothelial cells. It acts on two types of receptors, ETA (present on smooth muscle cells) and ETB (present on vascular endothelial cells). Stimulation of ETA receptors results in vasoconstriction via calcium influx whereas ETB causes vasodilation via stimulating NO release from endothelial cells. Selective blockade of ETA receptors leads to pulmonary vasodilation inside the fetus.

Initiation of respiration at birth replaces fluid-filled alveoli with air resulting in increased arterial oxygen tension. This results in rapid and marked decrease in PVR shortly after birth, leading to 8–10 folds increase in pulmonary blood flow. This leads to increase in pulmonary venous return and left atrial pressure promoting closure of foramen ovale. Simultaneous clamping of umbilical cord removes low resistance placental circulation, thus increasing systemic vascular resistance (SVR). The resulting decline in PVR or SVR ratio leads to steady increase in pulmonary blood flow and oxygen uptake in the lung. As soon as PVR falls below systemic levels, blood flow through ductus arteriosus reverses. This is followed by functional closure of ductus arteriosus

within first several hours after birth. Closure results in separation of pulmonary from systemic circulation leading to establishment of normal postnatal circulatory pattern. PVR continues to drop at a relatively slower rate over the next several weeks to reach adult levels.

This process of transition at birth depends on several factors. Increase in arterial oxygen tension is the most important among them which decreases PVR. Clearance of fetal lung fluid, expansion of the lung to normal resting volume and shear stress resulting from increased pulmonary blood flow also contributes to pulmonary vasodilation. All these factors promote release of pulmonary vasodilators including NO and PGI<sub>2</sub> (Fig. 1).

NO production is primarily mediated by increase in arterial oxygen saturation. Oxygen stimulates endothelial nitric oxide synthase (eNOS) which converts L-arginine to L-citrulline inside the endothelial cells of pulmonary artery and releases NO. Increase in synthesis and release of ATP from red blood cells also indirectly stimulates NO production inside endothelial cells. NO stimulates soluble guanylate cyclase (sGC) in the vascular smooth muscle cell, resulting in conversion of guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP). An increase in intracellular cGMP levels causes vascular smooth muscle relaxation by decreasing calcium influx. Type 5 phosphodiesterase (PDE-5) in the vascular smooth muscle cell degrades cGMP, thus limiting vasodilation. Reactive oxygen species (ROS) like superoxide may cause pulmonary vasoconstriction by scavenging NO molecules inside endothelial cells. NO is not stored inside the cells. Its increased synthesis at birth reflects increased

**Figure 1** Mechanism of endothelium-dependent pulmonary vasodilation at birth. Nitric oxide (NO) and prostacyclin (PGI<sub>2</sub>) are released in response to birth-related stimuli. NO and PGI<sub>2</sub> increase the cyclic guanosine monophosphate (cGMP) and cyclic adenosine monophosphate (cAMP) levels in the smooth muscle cell. Type 5 and type 3 phosphodiesterases (PDEs) degrade these cyclic nucleotides. A decrease in intracellular Ca<sup>2+</sup> levels leads to relaxation of vascular smooth muscle. NO levels are decreased by asymmetric dimethyl arginine (ADMA), superoxide (O<sub>2</sub><sup>-</sup>), and ET-1. Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit cyclo-oxygenase (COX). AA, arachidonic acid; eNOS, endothelial nitric oxide synthase; GMP, guanosine monophosphate; GTP, guanosine triphosphate; PGI<sub>2</sub>, prostacyclin; sGC, soluble guanylate cyclase; VEGF, vascular endothelial growth factor.

Source: Berger S, Konduri GG. Pulmonary hypertension in children: the twenty-first century. *Pediatr Clin North Am.* 2006;53:961-87. Reproduced with permission from Elsevier.

production of eNOS enzyme, which primarily takes place during late gestation period inside the fetus. NO also promotes growth of pulmonary vessels in utero in response to vascular endothelial growth factor (VEGF).

Prostacyclin is another potent pulmonary vasodilator. Stimulus at birth converts arachidonic acid to PGI<sub>2</sub> with the help of cyclooxygenase enzyme. PGI<sub>2</sub> acts in a similar fashion like NO-cGMP pathway and activates the enzyme adenylate cyclase in the vascular smooth muscle cell, which converts ATP to cyclic adenosine monophosphate (cAMP). An increase in intracellular cAMP levels causes vascular smooth muscle relaxation by decreasing calcium influx. Type 3 phosphodiesterase (PDE-3) like PDE-5 keeps a check on cGMP levels, thus limiting vasodilation. Thus, intervention which increases arterial oxygen saturation, NO, sGC, PGI<sub>2</sub> levels and decreases activity of PDE-5 and PDE-3, will have potential role in the management of PPHN. Similarly, blockade of ETA receptors and inhibitors of ROS will also help in decreasing PVR.

## EPIDEMIOLOGY

The prevalence of PPHN varies from 0.4 to 6.8 per 1,000 livebirths in developed countries. However, there is lack of data from developing countries. It is likely that PPHN occurs more frequently in this setting due to high incidence of perinatal asphyxia and meconium aspiration syndrome (MAS). PPHN primarily affects infants who are more than or equal to 34 weeks gestation although a very small proportion of very preterm infants also develop this disease.

## ETIOLOGY

Pulmonary hypertension of the newborn may be idiopathic (10%) or secondary to diverse neonatal conditions (**Fig. 2**). Perinatal asphyxia and MAS are two most common associated diagnoses. Others include various pulmonary parenchymal diseases including respiratory distress syndrome (RDS), transient tachypnea of newborn, pneumonia and/or sepsis. Pulmonary hypoplasia secondary to congenital diaphragmatic hernia (CDH) also leads to development of PPHN. Rare causes of intractable PPHN includes alveolar capillary dysplasia (ACD) and RDS secondary to mutations in surfactant protein B gene or ATP-binding cassette protein member 3.

Various antenatal and perinatal risk factors have been reported in association with PPHN. These include maternal smoking, consumption of aspirin or any other nonsteroidal anti-inflammatory drugs (NSAIDs) during pregnancy, intake of selective serotonin reuptake inhibitors (SSRIs), maternal fever, prolonged rupture of membranes, meconium-stained amniotic fluid and birth by cesarean delivery.

Recently, genetic predisposition has also been associated with increased risk of PPHN. These include specific polymorphism of carbamoyl phosphate synthetase gene, diminished expression of eNOS expression and variations in corticotropin-releasing hormone and its binding protein.

## PATHOGENESIS

Pulmonary hypertension of the newborn is a syndrome which is characterized by sustained elevation of PVR leading to right to left extrapulmonary shunting of blood across ductus arteriosus and/or foramen ovale to systemic circulation resulting in hypoxemia. Three types of abnormalities of the pulmonary vasculature occur in PPHN: underdevelopment, maldevelopment or vascular remodeling, and maladaptation (**Box 1**). However, this compartmentalization is imprecise and most patients actually have overlapping changes.

**Figure 2** Various etiological factors causing PPHN and hemodynamic changes in PPHN. Surfactant deficiency (RDS) or inactivation (MAS or pneumonia) results in parenchymal lung disease and ventilation-perfusion (V/Q) mismatch. Increased PVR results in reduced pulmonary blood flow and right-to-left shunt through PDA and/or PFO. Pulmonary hypertension is often associated with systemic hypotension with septal deviation to the left. Cardiac dysfunction secondary to asphyxia, sepsis or CDH may complicate PPHN. Parenchymal lung disease secondary to RDS, pneumonia, transient tachypnea of newborn (TTN), pneumonia, and atelectasis can result in V/Q mismatch and hypoxemia and PPHN. Idiopathic or “black-lung” PPHN is not associated with parenchymal lung disease and results in reduced pulmonary blood flow with pulmonary vascular remodeling. Pulmonary hypoplasia secondary to CDH or due to oligohydramnios (prolonged leakage of fluid or reduced production due to renal compromise) causes alveolar and vascular hypoplasia and PPHN. The right subclavian artery (and blood flowing to the right upper extremity) is always preductal. The left subclavian artery may be preductal, juxtaductal or postductal. Hence, preductal oxygen saturations should be obtained from the right upper extremity. *Abbreviations:* PA, pulmonary artery; RV, right ventricle; LV, left ventricle; TR, tricuspid regurgitation; RA, right atrium; LA, left atrium; PDA, patent ductus arteriosus; PFO, patent foramen ovale.

*Source:* Nair J, Lakshminrusimha S. Update on PPHN: mechanisms and treatment. *Semin Perinatol.* 2014;38:78-91. Reproduced with Permission from Elsevier.

- **Underdevelopment** This occurs in setting of underdeveloped lungs resulting in hypoplastic pulmonary vasculature. Here, the cross-sectional area of the pulmonary vasculature is reduced, resulting in a relatively fixed elevation of PVR. Only small degree of postnatal pulmonary vasodilation can occur resulting in high risk of mortality. This pathology occurs in pulmonary hypoplasia which may be seen as an isolated anomaly or in association with CDH, oligohydramnios syndrome or renal agenesis.

Few patients with CDH also have associated left ventricular (LV) hypoplasia or dysfunction. LV dysfunction results in pulmonary venous hypertension, which in turn increases pulmonary arterial hypertension. This results in severe PPHN unresponsive to conventional management.

**BOX 1 Mechanism of persistent pulmonary hypertension of the newborn***Underdevelopment/hypoplastic pulmonary vasculature*

- Congenital diaphragmatic hernia
- Pulmonary hypoplasia

*Maldevelopment/vascular remodeling*

- Idiopathic PPHN
- NSAID intake during pregnancy

*Maladaptation*

- Meconium aspiration syndrome
- Perinatal asphyxia
- Sepsis
- Pneumonia
- Respiratory distress syndrome
- Transient tachypnea of newborn

Abbreviations: PPHN, persistent pulmonary hypertension of the newborn; NSAID, nonsteroidal anti-inflammatory drug.

- **Maldevelopment or vascular remodeling** Here the pulmonary vessels are normal in number along with the normally developed lungs. However, abnormal muscularization of normally nonmuscular intra-acinar arteries, increased smooth muscle thickness of pulmonary arterioles and excessive extracellular matrix surrounding these vessels results in pulmonary vascular remodeling which leads to elevation of PVR. One possible stimulus leading to vascular remodeling is fetal hypoxemia. It causes release of humoral growth factors from hypoxia-damaged endothelial cells resulting in overgrowth of smooth muscle cells in pulmonary vasculature. Excessive perfusion of fetal pulmonary vasculature due to premature closure of ductus arteriosus by NSAID intake during pregnancy also results in pulmonary vascular remodeling. Vascular remodeling is classically seen in idiopathic (or black lung) PPHN.
- **Maladaptation** Here the structure and number of pulmonary vessels is normal; however, increased levels of pulmonary vasoconstrictors along with low production of endogenous vasodilators causes active pulmonary vasoconstriction. This is the likely mechanism in PPHN secondary to perinatal asphyxia, sepsis, MAS and other pulmonary parenchymal diseases. Patients with MAS have ventilation-perfusion (V/Q) mismatch due to meconium plugging, surfactant inactivation and lung inflammation. Similarly, alveolar collapse leads to impairment of oxygenation in various other pulmonary parenchymal diseases too. Resulting hypoxia along with hypercapnia and acidosis leads to increase in PVR. LV dysfunction along with acidosis also contributes to increase in PVR in perinatal asphyxia and sepsis. Polycythemia also results in PPHN by increasing blood viscosity.

## PULMONARY HYPERTENSION IN PREMATURE INFANTS

Although PPHN is a disease of late preterm and term infants, it is increasingly being recognized in preterm infants, especially with BPD. A prospective study of 765 infants of less than or equal to 32 weeks gestation found echocardiographic proven PPHN in 2.2% cases. There was prolonged premature rupture of membranes in all infants who developed PPHN. Intrauterine growth restriction, fetal inflammation and ventilator induced lung injury (VILI) result in impaired angiogenesis and abnormal lung development in infants with BPD. Around one-third of these infants develop

pulmonary hypertension later on during the hospital stay or after discharge from neonatal unit.

## CLINICAL FEATURES

Infants with PPHN generally present with respiratory distress and marked central cyanosis usually within first few hours after birth. There may be associated signs of perinatal asphyxia or meconium staining. Appearance of labile saturation or disproportionate hypoxemia, especially in patients being treated for primary lung diseases, also points towards development of secondary PPHN. Cardiac examination may reveal prominent precordial impulse, a single or narrowly split and accentuated S<sub>2</sub> and sometimes a systolic murmur due to tricuspid regurgitation.

Presence of right to left shunt across ductus arteriosus results in differential cyanosis. This is detected by a gradient in the preductal (right extremity) and postductal (any of the lower limbs) arterial oxygenation. Difference of more than 20 mm Hg in PaO<sub>2</sub> or more than 10% in saturation between preductal and postductal values suggests PPHN. However, its absence does not rule it out as a subset of patients have shunting only across foramen ovale resulting in no gradient. A similar gradient between preductal and postductal arterial oxygenation can also be present in duct-dependent systemic blood flow lesions including hypoplastic left heart syndrome, critical aortic stenosis, coarctation of aorta and interrupted aortic arch.

## DIFFERENTIAL DIAGNOSIS

Congenital heart disease (CHD), severe uncomplicated pulmonary parenchymal disease and sepsis are the most common differential diagnoses in a case of PPHN. Presence of differential pulse volume between upper and lower extremities, generalized weak pulse, grade 3+ murmur, pulmonary edema and cardiomegaly favors CHD. Rapid improvement with supplemental oxygen and/or mechanical ventilation suggests primary lung disease. However, this may not be obvious with severe parenchymal disease. Moreover, most infants with PPHN have transient improvement with supplemental oxygen and/or mechanical ventilation, making it difficult to differentiate these two entities on clinical ground.

## APPROACH TO DIAGNOSIS

Chest radiograph (CXR) and arterial blood gas (ABG) are two foremost investigations done in a case of suspected PPHN. CXR shows variable findings depending on the underlying diagnosis such as RDS and MAS. In general, the degree of hypoxemia is disproportionate to the radiographic findings and it is more so in a case of idiopathic PPHN, where there are no parenchymal infiltrates with oligemic lung fields. Cardiac silhouette is normal with normal to low pulmonary blood flow. ABG reveals hypoxemia (PaO<sub>2</sub> < 50 mm Hg). Because PPHN is a labile disease, documentation of normal arterial PaO<sub>2</sub> at some point during the course of disease does help in excluding cyanotic CHD. Similarly, many infants with PPHN have at least one measurement of PaO<sub>2</sub> more than 100 mm Hg on 100% FiO<sub>2</sub> early in the course of their illness, which helps in differentiating it from cyanotic CHD. Echocardiography (ECHO) is the gold standard test to diagnose PPHN. It not only rules out CHD but also determines the predominant direction of shunting at foramen ovale and/or ductus arteriosus and assesses LV function. Interventricular septal flattening or bowing towards left side and presence of tricuspid regurgitation suggests PPHN. However, the diagnosis of PPHN requires documentation of predominant right to left shunting at atrial and/or ductal level. Doppler velocity measurement of tricuspid regurgitation jet helps in assessing pulmonary arterial pressure.

The careful assessment of the direction of shunts provides invaluable information and helps in the management of PPHN. Predominant right to left shunting at ductal level along with left to right shunting at foramen ovale suggests LV dysfunction with pulmonary venous hypertension as seen in CDH. Pulmonary vasodilation alone without improving LV dysfunction will result in pulmonary edema in such a situation. Duct-dependent systemic blood flow lesions also have similar shunt pattern. Predominant left to right shunting at ductal level and right to left shunt at atrial level suggest duct-dependent pulmonary blood flow lesions such as critical pulmonary stenosis.

## MANAGEMENT

Our aim is to reverse abnormally increased PVR and to maintain adequate oxygenation till it normalizes. This can be achieved by preventing factors which aggravates pulmonary arterial hypertension, optimizing lung volume, maintaining systemic circulation, treating underlying disease and using pulmonary vasodilators (**Box 2**). Once stabilization is achieved, supportive measures should be gradually tapered to prevent rebound pulmonary hypertension.

### General Supportive Care

It is important to maintain euthermia and to correct metabolic abnormalities, such as hypoglycemia and hypocalcemia as these can impair cardiac contractility. Hemoglobin should be normalized to optimize oxygen delivery. Polycythemia needs to be corrected. Activities should be clustered to minimize handling. Auditory and visual disturbance should also be minimized by covering eyes and decreasing environmental noise level respectively.

### Sedation/Analgesia and Skeletal Muscle Relaxant

Dyssynchronous breathing in patients on mechanical ventilation causes agitation resulting in catecholamine release which may increase PVR. So, fentanyl 1 hour (1–5 µg/kg/h) or morphine (loading dose: 100–150 µg/kg over 1 hour, followed by 10–20 µg/kg/h, IV) is generally used to facilitate ventilation and to minimize fluctuations in PVR. However, there is no randomized controlled trial (RCT) to support this practice. Pancuronium, a skeletal muscle relaxant, is occasionally used to achieve full synchronization. However, its use is associated with various adverse effects including hypotension edema and deterioration in lung function. Moreover, it has resulted in increased incidence of subsequent hearing loss. Therefore, its use should be strictly restricted.

### Hyperventilation and Alkali Therapy

Low pH causes pulmonary vasoconstriction. Both hyperventilation and alkali therapy (sodium bicarbonate) result in transient improvement by making the pH alkaline. However, prolonged alkalosis paradoxically increases pulmonary tone and permeability. Alkali therapy has been associated with increased use of extracorporeal membrane oxygenation (ECMO) and increased need of oxygen at day 28 of life. Cerebral vasoconstriction due to alkalosis has resulted in increased incidence of sensorineural hearing loss (SNHL) in survivors of PPHN. High tidal volume used to achieve hyperventilation causes lung injury resulting in increased incidence of BPD. Thus, in the absence of any sustained benefit and with availability of iNO, therapeutic alkalosis is no longer recommended. However, sodium bicarbonate infusion is still being practiced in many centers primarily to correct severe metabolic acidosis. This practice is controversial in the absence of any RCT. Careful attention should be paid to excess sodium load and increasing PaCO<sub>2</sub> levels while instituting this therapy.

### Systemic Circulation

Persistent pulmonary hypertension is often complicated by systemic hypotension because of multiple reasons including

## BOX 2 Treatment of persistent pulmonary hypertension of the newborn

### General supportive care

- Maintain normal temperature
- Correct metabolic abnormalities
  - Hypoglycemia, hypocalcemia, electrolyte imbalance, anemia and polycythemia
- Ensure minimal stimulation
  - Minimize handling
  - Cluster activities
  - Minimize auditory and visual disturbance

### Adequate sedation and analgesia

- Fentanyl, morphine sulfate

### Skeletal muscle relaxant (rarely required)

- Pancuronium

### Maintenance of systemic circulation

- Volume expander
  - Normal saline
- Cardiotonic agents
  - Dobutamine
  - Dopamine
  - Epinephrine

### Specific treatment of underlying disorder

- Surfactant
- Antimicrobial agents

### Supplemental oxygen

#### Mechanical ventilation (emphasis on 'gentle ventilation' to achieve 'optimal' lung inflation)

- Conventional ventilation
- High frequency ventilation

### Pulmonary vasodilators

- Selective pulmonary vasodilator
  - Inhaled nitric oxide (FDA approved)
- Nonselective pulmonary vasodilator
  - Phosphodiesterase 3 inhibitor—Sildenafil
  - Phosphodiesterase 5 inhibitor—Milrinone
  - Prostacyclin analogues—Iloprost
  - Endothelin receptor antagonist—Bosentan
  - Nonspecific—magnesium sulfate

### Extracorporeal membrane oxygenation

#### Newer therapies

- Free radical scavenger
- Nicotinamide-adenine dinucleotide phosphate oxidase inhibitor
- Recombinant human superoxide dismutase
- Soluble guanylate cyclase (sGC) stimulator

myocardial depression due to asphyxia, decreased venous return due to high mean airway pressure and by the disease (sepsis or pneumonia) per se. Systemic hypotension may further impair oxygen delivery by aggravating right to left shunt. So, it is important to maintain adequate cardiac output to optimize tissue perfusion. Functional ECHO helps in assessing cardiac output but is not universally available. Trend of vitals, especially blood pressure, urine output and lactic acidosis helps in assessing systemic perfusion. In case of hypotension, fluid bolus with 0.9% normal saline (10 mL/kg over 30 min) is used to replenish intravascular volume. If hypotension still persists despite volume replacement, cardiotonic agents like dobutamine, dopamine and epinephrine are indicated. However, administration of dopamine and epinephrine in higher doses can itself lead to pulmonary vasoconstriction by stimulating pulmonary alpha adrenergic receptors. Moreover, overzealous use

of inotropes for increasing systemic blood pressure to reverse the right to left shunt can actually worsen the LV function by increasing its afterload.

## Oxygen

Oxygen is a potent pulmonary vasodilator and an important natural mediator resulting in decrease in PVR at birth. Therefore, supplemental oxygen is the foremost therapy in PPHN. However, animal studies have shown that hyperoxemia ( $\text{PaO}_2 > 80$  mm Hg) does not result in additional pulmonary vasodilation and even brief exposure to 100% oxygen results in increased contractility of pulmonary arteries and decreased response to NO. There are no clinical trials to guide optimal  $\text{PaO}_2$  or  $\text{SpO}_2$  targets in infants with PPHN. Maintaining preductal saturation in the range of 90–97% was associated with lowest PVR in newborn lambs with PPHN. Therefore, most units target preductal saturation and  $\text{PaO}_2$  between 90% and 97% and 50–80 mm Hg respectively in these patients.

## Mechanical Ventilation

Mechanical ventilation helps in recruitment of atelectatic alveoli which reduces V/Q mismatch and facilitates iNO delivery. Goal is to achieve target parameters (ABG—pH: 7.30–7.40,  $\text{PaO}_2$ : 50–70 mm Hg,  $\text{PaCO}_2$ : 40–50 mm Hg) by practicing *gentle ventilation* strategies including optimal positive end expiratory pressure (PEEP) and relatively low peak inspiratory pressure. There is no role of hyperventilation due to the increased risk of VILI and long-term neurodevelopmental impairments. Optimal lung is very crucial in overall management. This is because PVR is minimal when lung is inflated at its functional residual capacity. Care should be taken to avoid over distension as it increases PVR, impedes venous return and cause lung injury. Presence of 7–8 posterior intercostal spaces on CXR suggests optimal lung inflation and is achieved by instituting adequate PEEP and/or mean airway pressure. Conventional or high frequency ventilation (HFV) are the available modes of mechanical ventilation; however neither mode has shown to be more effective in preventing ECMO in infants with PPHN. Treatment with HFV plus iNO has resulted in greater improvement in oxygenation as compared to treatment with HFV or iNO alone in severe PPHN secondary to pulmonary parenchymal disease.

## Surfactant

Use of surfactant in treatment of PPHN secondary to lung diseases has increased over the last one decade. Surfactant causes alveolar expansion in parenchymal lung diseases. This reduces V/Q mismatch and facilitates iNO delivery. Cochrane systematic review (2 RCTs,  $n = 208$ ) has shown that the administration of surfactant reduces the need of ECMO in term infants with MAS (RR 0.64, 95% CI 0.46–0.91); however, it has no effect on mortality. A multicentric trial ( $n = 34$ ) conducted among term infants with severe respiratory failure due to parenchymal lung diseases and at risk for requiring ECMO treatment found that need for ECMO therapy was significantly less in the surfactant group as compared to placebo group ( $p = 0.038$ ). The benefit was greatest for infants with relatively mild disease [i.e. neonates with {oxygenation index (OI) of 15–22}]. However, there was no effect on infants with idiopathic PPHN.

## Inhaled Nitric Oxide

Inhaled nitric oxide is a selective pulmonary vasodilator unlike other pulmonary vasodilators and its response appears within minutes of starting therapy. It stimulates sGC activity resulting in increased cGMP levels (Fig. 1). It combines with hemoglobin after entering into pulmonary vessels and is rapidly converted

to methemoglobin and nitrate. As a result, there is little effect—systemic blood pressure (selective action) (Fig. 3). iNO enters only ventilated alveoli and dilates adjacent pulmonary arterioles. This results in redirection of pulmonary blood flow to well ventilated parts of lung, thus reducing V/Q mismatch (Fig. 3).

Inhaled nitric oxide was approved by FDA in 1999 for near-term and term infants with PPHN. Evidence of its use comes from large RCTs where iNO therapy has shown to decrease the need of ECMO without any effect on mortality, length of hospitalization or risk of neurodevelopmental impairment. The cochrane systematic review (6 RCTs,  $n = 753$ ) comparing iNO with placebo or standard care in late preterm and term infants with PPHN concluded that use of iNO was associated with significant reduction in death or need for ECMO (RR 0.65, 95% CI 0.55–0.76). This difference was entirely due to reduction in need for ECMO without any effect on mortality. Overall 50% of the infants responded to iNO therapy in these trials. However, the benefit did not extend to infants with CDH. In fact, the final outcome was slightly worse in this subgroup. Current evidence does not support the use of iNO in infants with CDH however; transient improvement with initiation of iNO in a subset of CDH patients suggests that this intervention might be useful in achieving partial stabilization before starting ECMO. Available evidence also does not support the use of iNO in infants less than 34 weeks gestation.

Oxygenation index [ $\text{OI} = (\text{mean airway pressure} \times \text{FiO}_2 \div \text{PaO}_2) \times 100$ ] is used to assess the severity of hypoxemia in PPHN. iNO is generally started once OI is more than or equal to 25. Early initiation of iNO at an OI of 15–25 has not reduced the need for ECMO while an OI of 40 is generally accepted as an indication for ECMO. Adequate alveolar recruitment should be ensured and CHD should be ruled out before initiating iNO therapy. ECHO is

**Figure 3** Effect of iNO on the pulmonary circulation. iNO reaches healthy alveoli, shown on the left, and diffuses to the adjacent pulmonary arteries to cause vasodilation. As NO reaches the lumen of the pulmonary artery, it is inactivated by Hb, limiting its effect to the pulmonary circulation. NO does not reach the atelectatic alveoli, shown on the right, maintaining constriction of the adjacent pulmonary arteries. Increased perfusion of the ventilated segments of the lung improves the V/Q match and oxygenation in parenchymal lung disease.

not mandatory but highly desirable before initiating iNO. However, it must be performed whenever there is clinical suspicion of underlying CHD.

Most RCTs support starting dose of 20 ppm. This was also the dose at which peak improvement in the pulmonary-to-systemic arterial pressure ratio was found among neonates with PPHN. Higher doses up to 80 ppm have been studied; however, found to be associated with more adverse effect (methemoglobinemia) with nonsignificant increase in response rate. Increase in  $\text{PaO}_2$  by more than 20 mm Hg or decrease in OI by 20% suggests clinical response and usually occurs within few minutes after starting iNO therapy. The potential adverse effects associated with iNO use are platelet dysfunction, methemoglobinemia and production of nitrates ( $\text{NO}_2$ ). Therefore, levels of these toxic metabolites should be monitored while patient is on iNO therapy. Once oxygenation improves, weaning should be gradually done to prevent rebound pulmonary hypertension. Tapering should be started once  $\text{FiO}_2$  is less than 60% and done at the rate of 5 ppm every 2–4 hourly. Once iNO dose is 5 ppm, gradual weaning at the rate of 1 ppm q 4–6 hourly is done.

Around 40% infants with PPHN do not respond or maintain a sustained response to iNO therapy. One should carefully analyze the relative role of parenchymal lung disease, pulmonary vascular disease and cardiac dysfunction in nonresponders. Optimization of lung volume with use of surfactant and HFV in parenchymal lung diseases improves response rate to iNO therapy. Cardiac performance should be optimized in presence of LV dysfunction. Repeat ECHO should be done to rule out underlying CHD. Formation of ROS and nitrogen species can contribute to ill sustained response to iNO. ACD and presence of severe lung hypoplasia may also result in failure of iNO therapy.

### Sildenafil

High failure rate, occurrence of rebound pulmonary hypertension after stopping iNO and high cost has led to the search for other pulmonary vasodilators. PDE inhibitors are a group of drugs which results in increased levels of cAMP or cGMP (**Fig. 1**). This in turn causes pulmonary muscle cell relaxation. Sildenafil, a phosphodiesterase type 5 inhibitor is available in both oral (0.25–0.5 mg/kg/dose up to a maximum of 2 mg/kg/dose q 6 h) and intravenous (loading dose is 0.4 mg/kg/dose IV over 3 h followed by a continuous infusion of 0.07 mg/kg/hour for up to 7 days) preparation. The Cochrane review (3 RCTs,  $n = 77$ ) comparing oral sildenafil with placebo in term newborns with PPHN concluded that the use of sildenafil was associated with significant reduction in mortality (RR 0.20, 95% CI 0.07–0.57). However, all RCTs were conducted in resource limited settings where iNO and HFV facilities were not available. An open label dose-escalation trial ( $n = 36$ ) of intravenous sildenafil in patients with and without prior exposure to iNO found it to be effective in improving oxygenation. Though the use of sildenafil in neonatal population has not been approved by FDA, it is often used off-label in settings where iNO is unavailable. It is also used for augmenting iNO response in partial responders, in treating rebound pulmonary hypertension and in BPD patients with pulmonary hypertension. The concern with systemic vasodilators like sildenafil is its potential to cause systemic hypotension.

### Milrinone

Milrinone is an inodilator and inhibits PDE-3 enzyme (**Fig. 1**). It has shown to decrease pulmonary artery pressure in various

animal models. It acts synergistically with iNO and may decrease rebound pulmonary hypertension. Infants with PPHN refractory to iNO therapy have responded to milrinone in few case series. However, RCTs comparing milrinone with iNO are lacking. Its use can lead to systemic hypotension.

### Magnesium Sulfate ( $\text{MgSO}_4$ )

Magnesium inhibits depolarization of smooth muscle cells by modulating uptake and binding of calcium, thus promoting vasodilatation. Evidence of its use primarily comes from few case series where intravenous infusion of  $\text{MgSO}_4$  has been used due to nonavailability of iNO. One RCT ( $n = 25$ ) has compared intravenous  $\text{MgSO}_4$  with iNO in term infants with PPHN. There was no difference in the proportion of infants who responded primarily to either therapy. However, more number of infants responded to iNO after failing initial  $\text{MgSO}_4$  therapy as compared to those who were administered  $\text{MgSO}_4$  following a failed iNO therapy ( $p = 0.03$ ).

### Bosentan

Bosentan is ET-1 receptor blocker and has been used in adults with PPHN. Few case reports suggest that bosentan can improve oxygenation in infants with PPHN. There is only one published RCT in neonates with PPHN ( $n = 47$ ,  $\geq 34$  weeks and  $< 7$  days old) where oral bosentan (1 mg/kg/dose q 12 hours) has been compared with placebo in the setting where iNO facility was not available. Bosentan was found to be superior with overall favorable response in 87.5% cases in contrast to 20% in placebo group ( $p < 0.0001$ ). The main concern with its use is hepatotoxicity.

### Prostacyclin

Prostacyclin activates adenylate cyclase which in turn increases cAMP concentration. This triggers smooth muscle cell relaxation leading to vasodilation. Intravenous  $\text{PGI}_2$  have been used in adults in treatment of pulmonary hypertension. In a retrospective review, oral  $\text{PGI}_2$  analog has been shown to cause significant improvement in oxygenation in five neonates with PPHN who were refractory to HFV. However, the disadvantage of systemic therapy is its potential to cause hypotension. Therefore, inhaled form of  $\text{PGI}_2$  (iloprost) is being used which produces selective pulmonary vasodilatation. Infants with PPHN who were refractory to iNO therapy have shown improvement in oxygenation with the use of inhaled  $\text{PGI}_2$  in few case reports. However, clinical trials are lacking resulting in their limited use.

### Extracorporeal Membrane Oxygenation

Approximately 40% of infants with PPHN do not respond to conventional therapy and require ECMO. ECMO is a life-supporting therapy which involves diversion of blood from a major systemic vessel through a gas exchange device and back to a major vessel. It maintains tissue oxygenation and gives time for the lungs and heart to recover. Increasing use of HFV, surfactant and iNO has led to reduction in the need of ECMO. The Cochrane review (4 RCTs,  $n = 244$ ) that compared ECMO with conventional management in newborns with severe respiratory failure concluded that use of ECMO was associated with significant decreases in the mortality (RR 0.44; 95% CI 0.31–0.61). This effect was even more significant in infants without CDH (RR 0.33, 95% CI 0.21–0.53). However, this therapy is costly and labor-intensive with limited availability.

Most units start ECMO when OI is consistently more than or equal to 40. ECMO is restricted to infants who are more than

35 weeks and have potentially reversible lung condition with no significant intracranial injury or coagulopathy. Patients who do not improve on ECMO are likely to have irreversible lung conditions such as ACD or severe pulmonary hypoplasia.

### Newer Therapies

Elevated concentration of ROS due to increased activity of nicotinamide-adenine dinucleotide phosphate (NADPH) oxidase or diminished activity of endogenous superoxide dismutase promotes vasoconstriction. Preliminary data suggests attenuation of vasoconstriction and improvement in oxygenation with administration of NADPH oxidase inhibitors and recombinant human superoxide dismutase. Decreased activity cGMP in remodeled pulmonary vessels causes diminished response to both endogenous and exogenous NO. A new molecule that directly stimulates sGC at an NO-independent site may have a promising role.

### OUTCOME

The advent of iNO and ECMO therapy has markedly improved the survival (85–90%) of PPHN infants in the developed world. However, mortality is still quite high in developing countries due to scarcity of resources and delayed referral. Survivors of PPHN are at risk for SNHL and various other neurodevelopmental disabilities irrespective of the use of iNO or ECMO. Around one-third of the survivors of Neonatal Research Network trial of iNO had at least one disability in the form of either SNHL (14%) or cerebral palsy (11%) or mental developmental index less than 70 (23%) or psychomotor developmental index less than 70 (14%) at 18–24 months of chronological age. Five percent had visual impairment and 2% had blindness. Infants with CDH were more prone with almost 50% developing SNHL. Various other studies have found behavioral problems (26%) and IQ score less than 70 (9%) at 1–4 years and at school age respectively. These infants are also more prone for rehospitalization especially within 1 year after discharge and have increased requirement of bronchodilator therapy at 5–11 years of age.

### PREVENTION

Good antenatal care, timely referral, optimum delivery practices (avoiding late preterm, early term and post-term deliveries, good intrapartum fetal monitoring) and adequate resuscitation along with high index of suspicion, immediate attention and timely management of predisposing conditions can prevent PPHN to some extent.

### IN A NUTSHELL

1. Failure to achieve or sustain the normal decrease in PVR at birth results in PPHN.
2. Diverse set of disorders causing vascular dysfunction and remodeling results in PPHN.
3. PPHN primarily affects infants more than or equal to 34 weeks gestation.
4. It should always be suspected in the presence of underlying risk factors or in a newborn with central cyanosis. Disproportionate ventilator requirement and labile saturation points towards development of PPHN.
5. Difference of more than 20 mm Hg in PaO<sub>2</sub> or more than 10% in saturation between preductal and postductal values in absence of CHD suggest PPHN but its absence does not rule it out.
6. ECHO is the gold standard test to diagnose PPHN and to rule out CHD.
7. Clinical management requires holistic care including optimization of ventilation and systemic circulation for achieving successful outcome.
8. The only FDA-approved selective pulmonary vasodilator for infants more than 34 weeks gestation is iNO which works very well in combination with HFV.
9. There is a potential role of sildenafil and milrinone in resource limited setups. However, more evidence is required.
10. Neurodevelopmental impairment and pulmonary sequelae occur in around one-fourth of survivors, thus highlighting the need of intense multidisciplinary follow-up of these infants.

## Chapter 17.9

# Pulmonary Hemorrhage

Emily F Fishman, Rakesh Rao

Pulmonary hemorrhage (PH), described as early as in 1855 in preterm and term infants, is associated with high mortality and significant morbidity in survivors. It may manifest as minor bleeding in the endotracheal tubes in intubated patients, or as a life-threatening event with rapid deterioration resulting in respiratory compromise, cardiorespiratory collapse and even death. PH may remain occult and requires a high index of suspicion for rapid diagnosis and appropriate treatment.

## EPIDEMIOLOGY

Pulmonary hemorrhage varies inversely with gestational age with the highest incidence in infants at the limit of viability. The incidence of PH is reported between 1 and 11 per 1,000 livebirths and may be as high as 50 per 1,000 livebirths in high-risk population, such as infants with intrauterine or fetal growth restriction. PH is reported in 0.5–11.0% of very low birth weight infants (VLBW, < 1,500 g). The true incidence may vary according to the definition used.

With improving perinatal care and survival of VLBW infants, recent data from developing countries (Asia including India) suggest that PH may affect 8–32% of VLBW infants. Of importance, mortality with PH was reported in 50–82% of all preterm infants and in approximately 17–23% in term infants. PH was associated with near seven-fold higher risk of mortality in preterm infants less than 32 weeks gestation in one study.

## ETIOLOGY

A distinct bimodal distribution is seen with infants less than 35 weeks gestation developing PH within 72 hours of birth compared to a median age of 6 hours in infants more than 35 weeks gestation. However, the etiologies of PH in preterm and term infants vary with several factors predisposing VLBW infants and the more immature infants at higher risk (**Box 1**). Infants born at less than 26 weeks gestation, extremely low birthweight (ELBW, < 1,000 grams), lower Apgar scores at 1 and 5 minutes of age, and infants with more severe respiratory distress syndrome (RDS) are at higher risk for developing PH. The use of mechanical ventilation (associated with alveolar overdistension) is associated with a four-fold increased risk. Antenatal steroids used for fetal lung maturation are associated with a *decreased* risk of PH. Maternal cocaine use, multiple gestation, maternal antibiotic use and previous pregnancy loss have been associated with PH. However, other maternal factors, such as preeclampsia, cord prolapse, abruption and placenta previa have *not* been clearly identified as risk factors for PH after birth.

Fetal growth restriction [intrauterine growth restriction (IUGR)] and small for gestational infants are at particular risk for PH, an association that appears to be independent of other factors. A three-fold higher risk of PH has been reported in this population with one study noting near 100% mortality in preterm IUGR infants who developed PH.

Neonates with severe RDS are also at risk for pulmonary interstitial emphysema or pneumothorax. These complications may precede PH. Some believe that PH is a continuum of the severity of underlying lung disease.

PH is associated with surfactant use (described later). In vitro studies show that surfactant impairs coagulation, and paradoxically, blood and blood products cause surfactant inactivation.

### BOX 1 Risk factors associated with pulmonary hemorrhage

- *Maternal factors*
  - *Presurfactant era*: Breech delivery, multiple gestation
  - *Postsurfactant era*: Cesarean section, maternal antibiotic therapy, chorioamnionitis
- *Preterm infants*
  - Prematurity
  - Male gender
  - IUGR, small for gestation
  - Perinatal depression
  - Surfactant therapy
  - Patent ductus arteriosus
  - Metabolic acidosis
  - Hypothermia
  - Coagulopathy
  - Respiratory distress syndrome (severe)
  - *Air leak syndromes*: Pneumothorax, pulmonary interstitial emphysema
  - Mechanical ventilation
  - Septicemia
- *Term infants*
  - Meconium aspiration
  - Perinatal hypoxia/depression
  - Hypotension
  - Mechanical ventilation
  - Coagulopathy
  - Septicemia
- *Urea cycle disorders*
- *Rare*
  - Listeriosis, *H. influenzae*
  - Congenital CMV
  - Fungal infections

Abbreviations: IUGR, intrauterine growth restriction; CMV, cytomegalovirus

Patent ductus arteriosus (PDA) is a frequent complication of preterm birth. Presence of a hemodynamically significant PDA (hsPDA) increases risk of PH due to pulmonary overcirculation, left ventricular failure and elevated pulmonary capillary transmural pressure (see section on pathophysiology later). Preventing hsPDA could therefore decrease PH. A trial of prophylactic indomethacin showed a near 50% decrease in the incidence of PDA in the indomethacin compared to the placebo-treated group. *Post hoc* analyses from this study, however, showed a 35% decrease in PH in the prophylactic indomethacin arm only during the first week of life attributable to closure of PDA.

Rapid volume expansion (causing an increase in pulmonary blood flow and opening of the PDA) and use of blood and blood products (albumin) have been associated with PH in the more immature infants. Other factors associated with PH in preterm infants include histological chorioamnionitis, multiple births, breech presentation and cesarean section.

Metabolic acidosis is often associated with PH. Metabolic acidosis in preterm infants is associated with hypothermia (core temperature < 36°C), hypoglycemia, septicemia and disseminated intravascular coagulation, and often precedes PH. Perinatal depression necessitating aggressive resuscitation and hypoxia also lead to metabolic acidosis. Infants with PH develop secondary hypoxemia with respiratory and metabolic acidosis.

In the developing world, hypothermia in the delivery room or soon after birth is a significant complication attributable to varying delivery practices. Term infants can drop their core body temperature by 0.1–0.3°C per minute without intervention; preterm infants are at an even higher risk of hypothermia. Hypothermia leads to cold stress and secondary hypoglycemia, hypoxia, metabolic acidosis and coagulation defects. In vitro experiments

show that cold injury causes platelet aggregation which can lead to functional thrombocytopenia and potentially contribute to PH.

Any coagulopathy increases the risk for PH including inherited coagulation disorders. von Willebrand disease has been identified in infants that died from idiopathic PH. In a study of infants less than 34 weeks gestation, thrombocytopenia with platelet count of less than  $100,000 \times 10^6/\text{liter}$  was associated with four-fold increased risk of PH. PH has, however, rarely been reported in infants with hemorrhagic disease of newborn or hemophilia.

PH in late preterm and term infants are often related to antenatal and perinatal factors. PH is associated with intrauterine and perinatal hypoxia/depression, meconium aspiration syndrome (associated with surfactant inactivation and air leaks) and mechanical ventilation, and occurs within the first 6–12 hours of life. PH can follow airway trauma during endotracheal intubation. In addition, infants that require extracorporeal membrane oxygenation (ECMO) are at risk for PH since ECMO therapy requires systemic anticoagulation.

Rarely, PH has also been attributed to bacterial, viral and fungal infections [*Listeria*, *H. influenzae* and congenital cytomegalovirus (CMV), congenital heart diseases (aortopulmonary window)] and diffuse pulmonary embolism with drug/lipid micro-aggregates. Urea cycle defects such as ornithine transcarbamylase (OTC) deficiency can present with respiratory distress and PH usually after first day of life. Lastly, PH may be idiopathic in nature.

## PATHOPHYSIOLOGY

Initially believed to be frank bleeding into the lungs and airways, PH fluid composition studies revealed the contents to be more consistent with bloody pulmonary edema. PH lung effluents show presence of smaller molecular weight plasma proteins and lower hematocrit (15–20% lower) in comparison to a peripheral blood sample. Frank blood is more likely to be seen with aspirated blood or trauma after intubation.

Although the exact pathophysiology has not been fully elucidated, *stress failure* of the pulmonary capillaries is believed to be a primary mechanism of PH (Fig. 1). The pulmonary gas exchange unit (PGU) consists of the alveolus lined by the thin-walled epithelium and the pulmonary capillary lined by the endothelium; the two are separated by the extracellular matrix (ECM) composed of the basement membranes of the two cell layers. The presence of type IV collagen in the ECM with its high tensile strength allows the PGU to adapt to the changes in pulmonary capillary pressure. Three forces govern the strength of the PGU, viz. (1) circumferential or hoop stress in the capillary wall that is related to the capillary *transmural* pressure (pressure difference between inside and outside the capillary) and alveolar radius; (2) longitudinal tension in the tissue elements of the alveolar wall due to lung inflation; and (3) surface tension in the alveolus that counteracts the increase in capillary transmural pressure. The disruption of the pulmonary capillary endothelium/alveolar epithelium, referred to as *stress failure*, due to elevated pulmonary capillary pressure (as with congestive failure), loss of surface tension or overdistension of the alveolus results in leakage of hemorrhagic fluid into the interstitium and the alveolus.

In preterm infants, PH is often associated with hspDA. In utero, placental blood bypasses the pulmonary circulation with two-thirds of blood flow being directed via the PDA into the systemic circulation. After birth and as pulmonary vascular resistance begins to fall (and after administration of surfactant), pulmonary blood flow increases and can exceed systemic circulation in the presence of hspDA. Kluckow et al. noted that in preterm infants less than 30 weeks gestational age, the presence of a large PDA (> 1.5 mm) as early as 6 hours after birth was associated with nearly one and half times as much median pulmonary blood flow prior to developing

**Figure 1** Pathogenesis of pulmonary hemorrhage. Alveolar air exchange unit with pulmonary alveoli (Palv) and adjacent capillary (Pcap). Two types of alveoli are shown, one well aerated (left) and one with presence of hyaline membranes (pink, right). The alveolar basement membrane (black) and epithelium (blue) is tightly opposed to the capillary basement membrane (red) and endothelium (blue) with the extracellular matrix in the interstitium (yellow). Three forces act to prevent capillary stress failure (see text for details) (Abbreviations: Ttmp, circumferential or hoop tension due to capillary transmural pressure; Tels, longitudinal alveolar wall tension due to lung inflation; ST, surface tension in the alveoli) Figure was adapted from West JB, Mathieu-Costello O. *Ann Rev Physiol.* 1999;61:543-72.

PH (328 mL/kg/min vs 238 mL/kg/min). Infants received less antenatal steroids but more often received surfactant prior to PH. The increase in pulmonary blood flow as the PDA becomes clinically significant causes *stress failure* of the pulmonary capillaries. This may also support why the majority of PH in the preterm population generally occurs between days 2 and 4 of life.

Overall surfactant use does not increase risk of PH. However, use of prophylactic surfactant versus rescue surfactant [relative risk (RR), 95% confidence interval (CI) = 3.28, 1.5–9.2], mode of administration (endotracheal vs. nebulized in fetal lamb studies), and the type of surfactant used—animal derived (bovine or porcine) versus synthetic surfactant (such as Exosurf) (RR, 95% CI = 0.73, 0.51–1.06)—influence PH. The decrease in surface tension following surfactant administration causes increased pulmonary blood flow and decreasing vascular resistance leading to increased *stress failure* of the pulmonary capillaries. Of note, in infants with RDS who *do not* receive surfactant, PH is most often noted when pulmonary compliance and blood flow improve following resolution of RDS.

Neonates with perinatal depression often develop myocardial dysfunction with resultant increase in left atrial and pulmonary venous pressures and elevated pulmonary capillary transmural pressure. Hyperoxia has also been reported as a cause of pulmonary capillary *stress failure*.

Histopathological evaluation of lungs in neonates with PH may show a range of pathology. On gross macroscopic examination, lung weight is usually increased often with obliteration of the lobar borders and presence of frank blood in the airways. Microscopically, scattered red blood cells in the interstitium, intra-alveolar or intraparenchymal spaces to frank blood in the airways may be seen in the absence of significant inflammation. In infants treated with surfactant, PH is present in the alveoli, whereas in infants without surfactant treatment, there is more hemorrhage present in the interstitial spaces.

## CLINICAL FEATURES

Although the commonly accepted definition of PH is the presence of hemorrhagic fluid in the lungs and airways, particularly in mechanically ventilated neonates, PH may remain occult when hemorrhage is limited to the interstitium and does not extend into the alveolar space. Others consider PH as the presence of endotracheal blood accompanied by respiratory decompensation requiring increased support [increase in oxygen requirement by at least 10%, need for increased peak inspiratory pressure (PIP) or positive end expiratory pressure (PEEP)] or need for intubation within 60 minutes of the event. Tracheal secretions can vary from being frothy, pink or blood tinged effluent can be frankly bloody. The hallmark of presentation is characterized by rapid deterioration of the neonate; but PH can have a more subtle clinical presentation.

The onset of symptoms can be acute or can manifest over several hours (**Table 1**). In nonintubated neonates, PH may be manifested as apnea, intermittent hypoxemia with desaturations and bradycardia, and increasing oxygen requirements. Additional physical examination findings may include tachypnea, respiratory distress with retractions, and decreased or coarse breath sounds. In neonates on mechanical ventilation, decreases in pulmonary compliance, increased airway resistance and ventilatory support to deliver adequate tidal volume may be noted. The presence of frothy, pink tinged to frank bloody secretions is usually indicative of PH. Blood gas measurements will reflect elevated  $p\text{CO}_2$ , low  $\text{PaO}_2$  and an increase in alveolar to arterial (A-a) gradient. In cases of massive PH, neonates may develop rapid signs of shock secondary to hypovolemia and anemia including changes in heart rate (tachycardia followed by bradycardia with rapid deterioration), hypotension and impaired perfusion (mottled skin appearance and prolonged capillary refill).

Since PDA is a known risk factor for PH, signs and symptoms of PDA such as tachycardia, widened pulse pressure, respiratory and metabolic acidosis, presence of a cardiac murmur and cardiomegaly on X-ray may also be present.

## DIFFERENTIAL DIAGNOSIS

The diagnosis of PH is usually clinical and should be strongly suspected in preterm and term neonates with risk factors identified previously. The timing of presentation in preterm (between days 2 and 4) and term (on day 1) infants remains of importance.

In the absence of bloody effluent in the airways, the diagnosis of PH is often difficult to make in preterm (ventilated and nonventilated) infants as the clinical symptoms and signs may be subtle and can often be attributed to other reasons. For example, increased work of breathing, changes in oxygenation and ventilation may be secondary to worsening underlying lung disease, development of air leak syndromes such as pneumothorax, pulmonary hypertension or due to opening of PDA. Apnea and bradycardia may be secondary to prematurity itself. In addition, PH may often be a harbinger of other problem in the preterm neonate such as infection or sepsis.

Infants that present with massive PH (respiratory decompensation requiring intubation or escalation of ventilator support secondary to hemorrhagic secretions) are more likely to have evidence of hemorrhage as a primary sign. Similar to infants with more insidious presentation, the differential diagnosis should include infection or sepsis, patent ductus arteriosus, air leak syndrome including pneumothorax, chronic lung disease (in chronically ventilated infants), trauma and pulmonary hypertension. In addition, one should also consider inherited coagulopathic disorders and hemolytic disease of the newborn.

**Table 1** Symptoms and signs of pulmonary hemorrhage

<i>Symptoms of pulmonary hemorrhage</i>	<i>Signs of pulmonary hemorrhage</i>
Nonspecific clinical change in a previously well infant	Increased secretions Frothy pink secretions Frankly bloody secretions
Respiratory distress, increased work of breathing Apnea Bradycardia and desaturations Increasing oxygen requirements	Change in pulmonary compliance Increased pressures with mechanical ventilation Increasing airway resistance
Bleeding from other sites	Signs of shock Bradycardia, tachycardia Hypotension, decrease in cardiac output Hypovolemic shock including change in heart rate, prolonged capillary refill Patent ductus arteriosus Wide pulse pressure, tachycardia
Symptoms of patent ductus arteriosus	Pallor/Anemia Decreases in hematocrit may not occur initially
Shock or acute cardiovascular collapse	<i>Laboratory tests:</i> • Blood gas – Hypoxia: Increased A-a gradient – Hypercarbia – Metabolic acidosis • <i>White cell counts:</i> Bandemia, leukopenia, leukocytosis, thrombocytopenia, elevated D-dimer, decreased fibrinogen, prolonged PT • <i>X-ray:</i> White out, new infiltrates • <i>Head sonogram:</i> Intraventricular hemorrhage • <i>Echocardiogram:</i> Patent ductus arteriosus, left ventricular failure

Abbreviation: PT, prothrombin time.

In term infants who were previously healthy, metabolic disorders such as urea cycle disorders should be considered. It is important to recognize that systemic to pulmonary shunting of blood can lead to pulmonary edema and hemorrhage. Therefore, infants should be evaluated for congenital heart disease including left to right cardiac shunts, left-sided obstructive cardiac lesions and congenital mitral stenosis, evidence of pulmonary venous hypertension or, rarely, cerebral arteriovenous malformations.

Other causes include direct trauma to airways with endotracheal intubation, vigorous suctioning and lung injury during placement of chest tube. Aspiration of maternal blood can be ruled out using Apt test.

## APPROACH TO DIAGNOSIS

Preterm infants with PH typically present with sudden respiratory deterioration with bloody secretions in the airways. As mentioned earlier, infants may become apneic or develop respiratory distress, develop bradycardia or become hypotensive and go into cardiac failure or shock. Initial assessment of the infant should include a full clinical examination to evaluate for the underlying reason for the clinical deterioration including signs of bleeding from other sites.

Laboratory investigation should include a chest radiograph. While it has a low sensitivity and specificity with no defined diagnostic features for PH, it can be useful to distinguish PH

from other causes such as pneumothorax. Other radiograph findings include diffuse or fluffy opacities, scattered haziness, focal consolidation and features of underlying lung disease. Cardiomegaly and evidence of pulmonary edema may also be present (**Figs 2A and B**).

Signs of PDA such as widened pulse pressure with decreased diastolic blood pressure or hyperdynamic precordium may be apparent. Measuring simultaneous pre- and postductal oxygen saturations (pulse oximeter probes on the infant's right hand/wrist and a second probe on either feet or toes) can identify right to left shunting via the PDA. This may also serve as a basic screening test for congenital heart disease in term infants. An echocardiogram can confirm presence of hsPDA, other congenital heart disease or pulmonary hypertension.

Additional evaluation for degree of bleeding should include serial hemoglobin and hematocrit to evaluate changes secondary to hemorrhage. Complete and differential white cell count for infection, blood gas to evaluate oxygenation and metabolic status, and coagulation profile including prothrombin time, platelet count, fibrinogen and D-dimers should be checked to evaluate for disseminated coagulation. Bacterial, viral or fungal cultures should be considered.

In term infants, ammonia levels should be checked to rule out urea cycle defect. In preterm infants, a head sonogram should be obtained as intraventricular hemorrhage is also often noted following PH.

## MANAGEMENT

### Stabilization

The initial management (**Box 2**) should be aimed at stabilization of vital signs via standard neonatal resuscitation (airway, breathing and circulation) and optimization of gas exchange. Airway management, particularly in the presence of visible blood in the airways, should include endotracheal intubation and placement on mechanical ventilation. If the neonate presents acutely with apnea and bradycardia or sudden cardiopulmonary collapse, control of airway with cardiac compressions and medications per standard resuscitation guidelines may be required. Noninvasive respiratory support such as continuous positive airway pressure (CPAP) may not be optimal in this situation. Further, suctioning the airway should be done as blood in the airways and alveoli decrease respiratory

compliance and increase airway resistance. Once intubated (or if PH develops in an intubated infant), the PEEP should be increased to 6–8 cm to provide tamponade effect. Caution should be exercised in raising PEEP further particularly in the more preterm infants as high PEEP may itself cause alveolar rupture, result in hypercarbia, impair venous return and decrease cardiac output. Oxygenation can further be optimized by increasing the concentration of inspired oxygen, increasing PIP and mean airway pressure (MAP). If increasing PEEP and MAP on conventional ventilator is not adequate, high frequency oscillatory ventilation (HFOV) can be used successfully to slow or reverse hemorrhagic edema, improve oxygenation and ventilation. HFOV has been successfully used to treat massive PH with improved survival compared to conventional ventilation.

### BOX 2 Management of acute pulmonary hemorrhage

- Consider intubation
- Mechanical ventilation
  - Increase PEEP to 6–8 cm
  - Consider high frequency ventilation
- Endotracheal epinephrine or adrenaline
  - 1:10,000 dilution
  - 0.1–1.0 mL/kg
    - Instill close to carina
    - Repeat until bleeding stops
- Consider\*
  - Recombinant activated factor VII (rFVIIa) 50 µg/kg twice a day for 2–3 days
  - Hemocoagulase 0.5 KU q 4–6 hours
- *Laboratory tests:* CBC with differential counts, coagulation profile (PT, PTT, fibrinogen, D-dimer), blood gas, ammonia, blood cultures
- Chest X-ray
- Echocardiogram
- Head ultrasound
- Serial chest X-rays, blood gas and metabolic monitoring
- Antibiotics
- Transfuse blood and blood products
- Consider surfactant once bleeding stops

\* Not sufficient data available to recommend as primary management.  
*Abbreviations:* CBC, complete blood count; PEEP, positive end expiratory pressure; PT, prothrombin time; PTT, partial thromboplastin time.

**Figures 2A and B** (A) 25-week gestation male (day of life: 1) with fine ground-glass opacities bilaterally consistent with hyaline membrane disease (postsurfactant); (B) Same infant (day of life: 2) following pulmonary hemorrhage. Note the extensive areas of new infiltrates, consolidation and air bronchograms. Also note the increase in the size of the cardiac silhouette and elevated left bronchus

## Maintenance of Circulation

Massive PH is associated with rapid exsanguination and may result in circulatory collapse. Fluid resuscitation with packed red blood cell transfusion or normal saline may be required for volume expansion to support circulation. Additionally, blood products such as platelets (for platelet dysfunction or thrombocytopenia) and fresh frozen plasma (for disseminated intravascular coagulation) may be warranted. Caution should be exercised as aggressive volume resuscitation may result in reopening of a PDA or precipitate cardiac failure and pulmonary edema.

## Drug Therapy

Evidence is limited regarding pharmacological treatment of PH, given the lack of randomized controlled trials. Endotracheal epinephrine or adrenaline (1:10,000 concentration or 0.1 mg per mL) in a range for dose of 0.1–1.0 mL/kg has been used most frequently to control the acute bleeding due to its vasoconstrictive and inotropic effects. Epinephrine should be instilled using a 6.5F or an 8F catheter (after suctioning) placed in the endotracheal tube as rapidly and as close to the carina (not beyond) as possible. Repeated doses may be necessary to control bleeding. Nebulized epinephrine has also been used with some success. A 4% cocaine solution instilled via the endotracheal tube has been used in the past, although this is no longer available.

Blood in the airways and alveoli increase airway resistance, decreases lung compliance and inactivates endogenous surfactant activity. Once bleeding is controlled (wait at least an hour after bleeding stops), repeat surfactant administration has been shown to improve pulmonary compliance, improve oxygenation and decrease the oxygenation index.

Activated recombinant factor VII (rFVIIa, a vitamin K-dependent glycoprotein that activates the extrinsic pathway), at a dose of 50 µg/kg twice daily for 2–3 days, has been shown in small clinical studies to be effective in controlling bleeding. It is more effective when coadministered with platelets. However, cerebral venous thrombosis has been reported as side effect in adults but not in neonates, hence caution should be exercised with its use.

Hemocoagulase (a purified enzyme mixture derived from the venom of South American viper, *Bothrops atrox*) converts prothrombin to thrombin and fibrinogen to fibrin, thereby decreasing bleeding time. Two small studies in neonates show that endotracheal administration of hemocoagulase [(0.5 KU (Klobusitzky unit) every 4–6 hours] may be effective in preventing and treating PH without significant adverse events. However, additional studies and availability of these drugs are needed to establish dose, frequency of administration and consistency of response before being recommended for routine use.

## Supportive Therapy

### Patent Ductus Arteriosus

As PDA is often antecedent to PH in the preterm population, it may be necessary to address closure of PDA once infant is stabilized. Medical treatment with indomethacin or ibuprofen may be attempted; ligation may be considered in the more critically sick neonate.

### Antibiotics

Infection and sepsis are often causes of PH as well as confounding factors in infants with acute decompensation. Broad spectrum

antibiotics based on the unit's bacteriological profile should be started while awaiting blood culture results.

### Others

Additional supportive care should include serial chest X-rays to evaluate pulmonary status; blood gas monitoring and correction of hypoxia and metabolic acid-base status, blood counts and coagulation profile (prothrombin time, platelet count, fibrinogen and D-dimers) for correction of disseminated coagulation. Fresh frozen plasma and other blood products may be needed. In term infants, if elevated ammonia levels suggest urea cycle disorder, intravenous dextrose and lipids along with sodium benzoate and sodium phenylacetate should be provided. Vitamin K may be administered if hemorrhagic disease of the newborn is suspected.

## OUTCOMES/PROGNOSTIC FACTORS

Despite advances in neonatal care, PH is a relative frequent complication and has high fatality in the most immature gestational age groups. PH in the developing countries has been identified a major cause of mortality in both term and preterm infants. Mortality rates over 50% have been noted in preterm infants but are lower in term infants. Majority of the mortality is acute and related to the severity of bleeding and severity of RDS in preterm infants; and to perinatal hypoxic injury and meconium aspiration in term infants.

In the short term, in one study in ELBW infants, those with PH who survived had higher rates of oxygen dependence at 28 days (RR 3.4), PDA (RR 3.1), seizures (RR 8.9) and periventricular leukomalacia (RR 2.2). Limited data on long-term neurodevelopment at 20 months in this cohort showed lower, but not statistically significant, psychomotor developmental scores than controls. Another study associated lower brain volume with preterm survivors with PH at term. However, similar data from the developing countries are currently lacking.

## PREVENTION

Existing literature suggests that maternal conditions are not significant contributors to PH after birth. However, obstetrical practices aimed at prevention of preterm birth—the population at highest risk of PH, are most likely to decrease the incidence of PH. Antenatal glucocorticoids improve pulmonary maturity and are associated with decreased incidence of PH, improve survival and decrease complications of prematurity.

After preterm birth, prophylactic indomethacin decreases the incidence of PH in the first week of life attributable to closure of PDA. Attention to fluid balance, limiting blood product use in the VLBW and ELBW infants in the first few days after birth is critical in minimizing pulmonary overcirculation with the resulting pulmonary edema and hemorrhage. Prompt attention should also be paid in treatment of a symptomatic PDA before PH can occur.

Trends towards decrease in PH have been noted with use of primary HFOV to treat RDS compared to conventional ventilation. In infants who develop PH, HFOV may be used to limit bleeding and improve ventilation and oxygenation.

### IN A NUTSHELL

1. Pulmonary hemorrhage (PH) is a complication seen in both preterm and term neonates. Incidence is inversely related to gestational age.
2. Antenatal administration of glucocorticoids decreases the risk of PH.
3. Fetal growth restriction/chronic intrauterine hypoxia or perinatal depression/hypoxia in both preterm and term infants increases the risk of PH.
4. PH in infants less than 35 weeks gestation occurs commonly between days 2 and 4 and is often associated with PDA and intraventricular hemorrhage. Hypothermia, metabolic acidosis, coagulopathy and prophylactic surfactant use increase the risk.
5. In near term and term infants, PH occurs within a few hours of birth and associated with meconium aspiration and hypoxia.
6. PH may present with subtle symptoms or with massive bleeding (into the lungs and airways) with acute decompensation requiring increased oxygen, increased ventilation, need for intubation or shock.
7. Management should include airway stabilization (intubation), endotracheal epinephrine and mechanical or high frequency oscillatory ventilation.
8. Evaluation should include underlying cardiac disease (such as patent ductus), initiation of broad spectrum antibiotics and assessment for infection, and close cardiorespiratory and metabolic monitoring.
9. Mortality in preterm infants with PH may be over 50%. Survivors are at higher risk for developing chronic lung disease and at a higher risk for neurodevelopmental impairment.

## Chapter 17.10

# Bronchopulmonary Dysplasia in Newborn

Samir Gupta, Sunil K Sinha

Improvement in neonatal intensive care has led to increasing survival of very immature babies, but a significant proportion of them also suffer from long-term morbidity including chronic lung disease (CLD), the severest form of which is called bronchopulmonary dysplasia (BPD). This is a multisystem disease and has important implications in terms of health resource utilization. Follow-up studies of these babies have demonstrated that BPD infants require frequent readmissions to the hospital in the first 2 years of life because of respiratory infections, asthma, and related problems, and they have persistent lung function abnormalities even as adolescents and young adults.

## EVOLUTION OF UNDERSTANDING OF BPD

The term bronchopulmonary dysplasia (BPD) was first coined by Northway et al. in 1967 and in its original description, this was seen in relatively mature babies, who were ventilated at high pressures, with high fractional concentration of inspired oxygen, resulting in lung overinflation with areas of atelectasis, cystic emphysema, and fibrosis as a result of significant interstitial and airway changes in the lungs. In contrast, BPD nowadays is seen primarily in very preterm newborns weighing less than 1000 g, who are born at 24–28 weeks of gestation. The histopathologic abnormalities of the *old* BPD have now been replaced by a *new* BPD with the large, simplified alveolar structures, variable interstitial cellularity and/or fibroproliferation. The clinical picture is also different. Today's premature babies developing BPD initially seem to have modest ventilatory and oxygen requirement and demonstrate a different radiographic picture, which shows diffuse haziness and a fine, lacy pattern. This difference between *Old* and *New* BPD can be better understood if one realizes that the lungs of infants born at 24–26 weeks gestation are in the early phases of lung development (canalicular and saccular stages) and, the alveolar and capillary development is further inhibited (developmental arrest) following exposure to the noxious effects of mechanical ventilation, oxygen exposure, and inflammation. In *new* BPD, airway and microvascular growth are also affected and this impaired angiogenesis was shown to be associated with decreased levels of vascular endothelial growth factor (VEGF) and angiogenic receptors, which are important components for normal structural development.

## DEFINITION

In the original form as described by Northway, definition of BPD was based on severity of respiratory illness associated with abnormality of chest X-ray appearance. Since then, however, this has changed and currently BPD is defined more on the basis of clinical severity and dependence on ambient oxygen and/or mechanical respiratory support at certain points in their clinical course, such as 28 days and 36 weeks postmenstrual age. Although oxygen supplementation has routinely been used as a surrogate for assessing the severity of underlying lung problem, this is subjective. It is not surprising that the prevalence of BPD varies significantly, depending on individual unit's clinical protocol and clinician's habit. To rectify this, Walsh et al. introduced the concept of *physiologic definition* of BPD in which infants, receiving less than 30% supplemental oxygen, were subjected to a stepwise 2%

reduction in supplemental oxygen until they were breathing in room air. The outcome of tests was defined as no BPD if oxygen saturation remained more than 88% for 60 minutes in room air or *BPD*, if saturation fell below 88% during this observation period. Throughout this period, these babies undergoing oxygen challenge were monitored for apnea, bradycardia and increased oxygen use. If any of these events occurred and required treatment, such babies were deemed to have failed and categorized as having *BPD*. Although still not perfect, at least this method does provide an objective assessment of the presence and severity of underlying lung problems. Most of the current studies have used this definition to compare outcome measures in clinical trials studying effect of any intervention related to prevention of BPD. This definition may still change in light of recent findings from large clinical trials suggesting that the optimal oxygen saturation range in preterm babies should be between 90 and 95%, and above 95% in those reaching *term gestation*. This recommendation is based on the findings from these large studies that lower concentration below 88% may be associated with increased mortality and adverse neurological outcome. NICHD—National Heart, Lung and Blood Institute further classified the BPD into Mild, Moderate or Severe on the duration and amount of oxygen required and the degree of respiratory support.

Arterial oxygenation is only one crude measure of lung function and it is very likely that in order to assess the full lung function, we may have to combine a number of tests measuring different aspects of lung function. This, however, may not be feasible in neonatal period as these tests are complex and practically difficult at such young age group. Until appropriate devices become available, clinicians will have to rely on simple markers to define populations at risk and predict later pulmonary outcomes.

## RISK FACTORS

A number of epidemiological studies have identified clinical risk factors which can modify the prevalence or severity of BPD. These include endogenous factors such as gestational immaturity, birth weight, male sex and family history of asthma. Genetic predisposition is another important factor which modifies the risk of BPD. Paucity of maternal glucocorticoids and endogenous surfactant certainly increases the risk of respiratory distress syndrome (RDS) and BPD. Administration of glucocorticoids clearly has advantages as this improves survival even amongst the tiniest of babies, but they do not seem to reduce the incidence of BPD. Recent studies have also indicated that prenatal factors including maternal smoking, pre-eclampsia, chorioamnionitis and intrauterine growth restriction are important risk factors for BPD.

Early neonatal pattern of lung disease, as assessed both clinically and radiologically, can identify babies at higher risk of BPD. The type of artificial respiratory support and its duration along with complications commonly seen in these babies including ventilator associated pneumonias (VAP), patent ductus arteriosus (PDA) and pulmonary interstitial emphysema (PIE) are known clinical risk factors as they exacerbate or prolong the respiratory illness and their ventilator dependence.

## ETIOPATHOGENESIS

Bronchopulmonary dysplasia (BPD) is multifactorial and an understanding of the *pulmonary injury sequence* may enable the development of strategies to interrupt this cascade. Essentially here are two main pathways leading to BPD. The first is intrinsic and is related to a *developmental arrest* of the lung resulting in diminished alveolarization. This results in inadequate surface area for gas exchange and impaired lung function, requiring the initiation of chronic ventilation and subsequent ventilator-induced

lung injury (VILI). Other factors include surfactant deficiency and the need to deal with a very compliant chest wall. Extrinsic factors also inhibit alveolarization and lung growth, and they include intrauterine cytokine exposure, antenatal and postnatal glucocorticoid treatment, insufficient nutrition, lung and systemic infections, and exposure to high concentrations of oxygen.

### Ventilator-induced Lung Injury (VILI)

Although a key component in the pulmonary injury sequence, VILI itself is multifactorial and mostly iatrogenic. The term *volutrauma* refers to injury related to overdistension or excessive stretching of the lung units (alveoli and smaller airways) by delivering too much gas (tidal volume). *Atelectotrauma*, in contrast, refers to the damage caused by insufficient tidal volumes (recruitment and de-recruitment of alveoli) associated with repetitive opening and closing of lung units. *Biotrauma* is a collective term to describe the adverse effects of infection and inflammation. *Rheotrauma* refers to damage caused by inappropriate airway flow. If the flow is excessive, it may cause inadvertent positive end expiratory pressure (PEEP), turbulence and ineffective gas exchange, and lung overinflation. On the other hand, if the flow is inadequate, it may lead to air hunger (flow starvation) and increased work of breathing. An understanding of the pathophysiology of VILI helps formulating ventilatory strategies aimed at reducing or preventing BPD in very small infants.

### Noninvasive Forms of Respiratory Support

Despite mechanical ventilation being the *standard* treatment for respiratory failure in newborns, there has been a recent upsurge in the use of *noninvasive* respiratory support, using single level support, such as continuous positive airway pressure (CPAP) and high flow nasal cannula (HFNC) or nasal intermittent positive pressure ventilation (NIPPV). CPAP is a form of distending pressure provided through a nasal interface. NIPPV provides intermittent positive pressure ventilation in addition to continuous distending pressure. The proponents of noninvasive ventilation claim that the absence of an endotracheal tube reduces the risk of trauma to the airways, reduces the risk of infection, and causes less acute and chronic lung damage, and thus prevents BPD. This, however, is not supported by the findings of large clinical trials. Yet, most neonatal units use noninvasive form of ventilation as it is simple to use and looks patient-friendly. Although long-term data regarding their safety is still not available, in short-term they at least appear to be safe. The choice of which type of respiratory support to use very much depends on individual unit's choice and personal experience.

### Continuous Positive Airway Pressure

Continuous Positive Airway Pressure supports the breathing of premature infants in a number of ways and can be delivered by a variety of devices and interfaces. CPAP devices can be categorized by the flow characteristics into *continuous flow systems*, such as bubble CPAP and ventilator-derived CPAP, and *variable flow system*, such as the infant flow driver and Benveniste (gas jet) valve CPAP. The meta-analysis of randomized trials comparing intubation and mechanical ventilation versus noninvasive respiratory support at birth reported a trend in favor of nasal CPAP in reducing BPD at 36 weeks (RR 0.91, 95% CI—0.07–0.01). Although statistically significant, its clinical significance remains unclear because the number needed to treat (NNT) to benefit from CPAP was 1 in 25.

### Volume-targeted Ventilation

Volume-targeted modalities of ventilation are relatively new to neonatal intensive care and represent a departure from traditional

time-cycled pressure limited ventilation (TCPLV) by focusing on tidal volume delivery to the lungs and allowing pressure to vary. Although there are only a few published randomized controlled clinical trials, thus far the evidence is highly encouraging. The consistency of tidal volume delivery during volume controlled ventilation (VCV) in the face of varying lung compliance and the auto-weaning of airway pressure may be clinically advantageous, especially in conditions in which lung compliance can change rapidly, such as after surfactant administration. A meta-analysis of volume-targeted ventilation reported a reduction in the total duration of ventilation, severe intraventricular hemorrhage and pneumothorax, and a strong trend toward a reduction in the incidence of BPD. Stability of tidal volume delivery may account for this, especially in extremely low birthweight infants, who are most at risk for sustaining complications associated with mechanical ventilation.

### High-frequency Ventilation

High-frequency ventilation (HFV), in contrast to conventional mechanical ventilation (CMV), uses extremely small tidal volumes delivered at rapid rates to affect gas exchange at lower alveolar pressures than CMV. There are two primary forms of HFV, high-frequency jet ventilation (HFJV), and high-frequency oscillatory ventilation (HFOV), as well as hybrid forms.

HFOV differs from HFJV in that even smaller tidal volumes are used at rates of 8–15 Hz. Mean airway pressure is used as a continuous distending pressure to inflate the lung to a static volume, and oscillations around this mean are used to affect gas exchange. Adjustments for oxygenation (via mean airway pressure) and ventilation (via amplitude) can be done independently of one another. Moreover, HFOV uses active exhalation, whereby gas is actively withdrawn from the lung during expiration.

A number of clinical studies of high frequency ventilation have reported long-term outcomes, although BPD was not the primary objective in most cases. Keszler et al. reported a reduced incidence of BPD and the need for home oxygen in infants treated with HFJV compared to CMV for uncomplicated RDS. A number of recent clinical trials compared HFOV to CMV in preterm infants with RDS. Two recently completed trials found differing results. The HIFI trial of Courtney et al. found a very slight reduction in BPD in babies receiving HFOV, although this could have reflected the fact that the control group was managed in synchronized intermittent mandatory ventilation (SIMV), which is not the ideal mode for acutely ill infants. The UKOS study found no difference in the incidence of BPD among infants receiving HFOV or conventional ventilation. Currently, there is insufficient evidence to recommend HFOV to reduce BPD.

### Permissive Hypercapnia

The rationale for using permissive hypercapnia, or in other words, *gentler ventilation*, using a low lung volume strategy, is that it may decrease volutrauma and lung injury, lessen the duration of mechanical ventilation, reduce alveolar ventilation and the complications of hypocapnia (especially reduced cerebral blood flow), and increase oxygen unloading at the tissue level (Bohr effect). The strategy of ventilating infants at a higher PaCO<sub>2</sub> level, termed permissive hypercapnia, is based upon the retrospective observation of Kraybill et al. in 1989. In a multicentric analysis of 235 preterm infants, these investigators demonstrated a higher incidence of BPD in those infants, who had lowest PaCO<sub>2</sub> on the second and fourth postnatal days, implying that they were *over ventilated*. Two prospective, randomized, controlled trials of permissive hypercapnia have been conducted. Although both studies demonstrated a statistically significant reduction in the duration of ventilation and other secondary outcome measures, the incidence of BPD did not differ.

## CLINICAL FEATURES AND DIAGNOSIS

Diagnosis of CLD and BPD is made on the composite of (a) background clinical information of prematurity, needing mechanical ventilation or other form of artificial respiratory support and oxygen therapy; (b) continuing respiratory distress at 21 days or 36 weeks postmenstrual age, and requiring oxygen and/or any form of mechanical respiratory support such as CPAP or HFNC; and (c) X-ray appearance showing features of atelectasis/over inflation or simply ground glass appearance (**Figs 1A and B**).

Severe cases of BPD may progress to develop pulmonary hypertension and cor pulmonale with features of right sided heart failure requiring cardiac and hemodynamic assessment. The underlying lung abnormality, in severe cases, may persist in later childhood showing features of atelectasis and obstructive airways disease, presenting as persistent cough, shortness of breath and need for inhaled bronchodilators. Such children also end up with frequent lower respiratory tract infection requiring hospitalization or visit to their doctor. Children with BPD often exhibit motor and cognitive developmental delay requiring specialist therapists.

## TREATMENT

### Ventilatory Strategies

The management of infants who have already developed BPD has not been studied fully and there is no clear strategy developed to deal with such babies. A suggested guideline for dealing with different lung issues is shown in **Table 1**. The infant with ventilator-dependent BPD presents many challenges to the clinician. Chronic respiratory insufficiency may result in aberrant gas exchange, manifest by severe hypercarbia, with marked renal compensation. The inexperienced clinician often attempts to make the baby conform to *physiologic* blood gases, and in doing so, may inadvertently overventilate the baby and unwittingly contribute to VILI. It is perhaps wiser to view the chest radiograph in the context of *What can I expect from these lungs?* and adjust one's expectations of blood gases accordingly.

Alteration in lung mechanics is another key feature of BPD. Reactive airways may result in increased pulmonary resistance. This may be treated empirically by adjustments in ventilator strategy, such as increasing PEEP and/or airway flow, or by using a modality with *variable* inspiratory flow, such as pressure control or pressure support compared to traditional *fixed* flow TCPLV. Lung compliance may also be abnormal. Ventilating the lung at an appropriate functional residual capacity, where incremental changes in pressure

recruit the most lung volume, is often a challenge. Assessing compliance at different levels of PEEP may be helpful in this regard. Alterations in resistance and compliance will alter the respiratory time constant, and sufficient expiratory time to avoid gas trapping and inadvertent PEEP must be provided. Decisions about the best mode or modality to ventilate a baby with BPD are best made on an individual basis. Theoretically, if lung disease is homogeneous, a modality such as pressure control might be advantageous, whereas heterogeneous lung disease should respond better to VCV because peak pressure and peak volume delivery occur at the end of inspiration, helping to make gas delivery more uniform throughout the lung. This will require clinical investigation.

Periodic assessment of cardiac function, looking for evidence of pulmonary hypertension, may also guide one's use of supplemental oxygen and establishment of appropriate ranges for  $\text{SaO}_2$ , although the optimal limits are yet to be established. All changes in strategy should be objectively assessed for response.

### Pharmacological Adjunctive Therapies

Once BPD is established, treatment is only supportive and aimed to alleviate the symptoms. Many such therapies, however, are based on *habit* rather than scientific evidence, and one should be aware of the usefulness and limitations of such therapies as they can be associated with adverse side effects. Commonly used therapeutic adjuncts in babies with BPD include steroids, diuretics, caffeine and Vitamin A. There are other adjuncts such as nitric oxide which have been tested in over 5000 babies with limited preventative or therapeutic benefits.

#### Antenatal Glucocorticoids

Because RDS results from surfactant deficiency, it only makes sense that efforts be made to induce endogenous surfactant production. Glucocorticoids are known to induce maturity of the lungs and this forms the rationale for using one course of glucocorticoids (usually betamethasone, given in two dosage at 12–24 hours, to mothers with imminent premature delivery). This does improve survival and severity of RDS, but there is no evidence that it reduces infant's pulmonary outcome or reduces the incidence of BPD.

The only other lung maturation strategy is a combination of corticosteroids and thyrotropin-releasing hormone (TRH). They are known to act synergistically, but ultimately there is no evidence that this combined therapy is of any use in preventing RDS or BPD. In fact they have toxic effects and, therefore, not used.

#### Postnatal Dexamethasone

Corticosteroids are anti-inflammatory and help in facilitating extubation in babies who are chronically ventilatory dependent.

**Figure 1A** Areas of hyperlucency in both lungs indicative of hyperinflation mixed with areas of distinct opacities suggestive of interstitial lung disease as characteristically seen in the severe form of BPD

**Figure 1B** Mild haziness covering both lungs as seen in early stages of RDS in a 3-week-old baby with no evidence of hyperinflation characteristic of new BPD

**Table 1** Respiratory management options for BPD

Issue	Strategy	Comments
Increased resistance	Variable inspiratory flow (pressure control or pressure support ventilation) Consider using higher PEEP to stent collapsing airways. Use largest comfortable endotracheal tube	Seen with airway injury and hyper-reactivity
Decreased compliance	Use higher PIP/PEEP. Consider high frequency ventilation. Avoid hyperinflation. Monitor tidal volumes	Reflects parenchymal lung injury
Heterogenous lung disease	Consider volume-targeted ventilation	Pressure-targeted flow patterns may contribute to ventilation/perfusion mismatch
Pulmonary hypertension	Consider pharmacotherapy. Liberalization of arterial oxygen tension	Limited evidence; follow echocardiogram
Hypercapnia	Re-evaluate gas exchange capability; allow higher carbon dioxide tension if pH is not deranged	Do not attempt to achieve <i>normal</i> gas exchange
Nutrition	Try to optimize caloric and fluid intake, but avoid excess carbohydrate or fat	Non-nitrogen calories will contribute to carbon dioxide production and respiratory load

Abbreviations: PIP, peak inspiratory pressure; PEEP, positive end expiratory pressure.

However, there have been concerns that excessive or prolonged use of dexamethasone could be associated with cerebral palsy and adverse neurodevelopmental outcome. In view of this, it only makes sense to adopt a cautious approach and use corticosteroids only in very select group of babies, who are still ventilatory dependent and unlikely to come off the ventilator. In such cases, dexamethasone can be used at the lowest dose for the shortest course possible with some beneficial effect. Considering the efficacy and associated systemic side effects of dexamethasone, studies have looked into the feasibility of giving steroids in a nebulized form. This, however, does not show any benefit either in terms of survival or incidence of BPD.

### Diuretics

Infants with RDS and BPD have a tendency to retain excess body fluids. This can lead to a deterioration in pulmonary function and need for further respiratory support, which in turn causes BPD (pulmonary injury sequence). In such cases use of diuretics along with fluid restriction might be theoretically beneficial. The commonly used diuretics in babies with RDS and BPD include: (a) combination of chlorothiazide and spironolactone; (b) furosemide; and (c) bumetanide.

Despite their widespread use, there are relatively few data assessing the meaningful value of diuretic therapy in BPD. Of all the adjunctive therapies used in preterm infants with BPD, diuretics therapy is one of the most commonly used or abused drugs without evidence of substantive benefit. Moreover, they can cause significant complications such as hypercalciuria and nephrocalcinosis leading to secondary complications. This, however, mostly resolves after cessation of diuretic therapy.

### Vitamin A Supplementation

Vitamin A is one of the few drugs which is known to have beneficial effect on growing tissue such as lungs. Babies born prematurely are deficient in vitamin A and this has been shown to be associated with BPD. A large randomized controlled trial among infants weighing less than 1000 g at birth showed a significant beneficial effect of intramuscular Vitamin A given at birth. Despite this, vitamin A is still not used regularly on most neonatal units probably because it requires intramuscular injection. Another trial of oral vitamin A therapy daily for four weeks in a similar population of infants failed to detect any beneficial effect. A meta-analysis involving a number of randomized controlled trials has suggested that vitamin A supplementation reduces risk of BPD at 36 weeks postmenstrual age (RR 0.87, 95% CI 0.77–0.98).

### Caffeine Therapy

Caffeine has traditionally been used for treatment of *apnea of prematurity*. It also facilitates extubation from mechanical ventilation. However, there were concerns that caffeine may be associated with adverse cerebral and intestinal blood flow velocity, thus increasing the risk of cerebral palsy and necrotizing enterocolitis (NEC). A large international trial showed caffeine therapy to significantly reduce risk of BPD (OR 0.63, 95% CI 0.52–0.76;  $p < 0.001$ ). Interestingly, BPD was not a primary outcome measure of this trial and, therefore, it is believed that the beneficial effect of Caffeine amongst ventilated babies came because of earlier extubation and shortened duration of ventilatory dependency. A subsequent analysis of data from this large study also confirmed

that caffeine when given early amongst babies who were receiving mechanical respiratory support was associated with better outcome compared to those in whom caffeine was administered either late or for other indications.

### IN A NUTSHELL

1. Bronchopulmonary dysplasia is a recognized sequel of preterm birth. With improving survival of infants at lower gestational ages, the prevalence is on the rise.
2. Pathological features of BPD include alveolar maldevelopment, with or without areas of pulmonary fibrosis. Assisted ventilation, infection/inflammation, oxygen administration and fluid overload are major identified risk factors in the evolution of BPD.
3. The prevention of BPD needs a multifocal approach by decreasing VILI through utilization of newer ventilatory strategies such as volume-controlled ventilation and the use of non-invasive forms of respiratory support in selected preterm babies. Many other therapies are still investigational and potentially dangerous and need further evidence before they can be routinely recommended. Determining the optimal strategy for infants with ventilator-dependent BPD is a work in progress, but a very necessary one in view of the number of affected infants.
4. Once established, BPD is associated with a number of adverse health consequences requiring input from a number of specialists including respiratory pediatrician, cardiologists, neurodevelopmental pediatrician, clinical psychologists and specialist therapists, such as physiotherapist, occupational therapists and dietician. Therefore, efforts should be aimed at preventing BPD rather than trying to cure it when it has already established.

# Section 18 NEONATAL MALFORMATIONS

**Section Editor** Siddarth Ramji

## Chapter 18.1

### Esophageal Atresia and Tracheoesophageal Fistula

*Yogesh Kumar Sarin, Shalini Sinha*

Esophageal atresia and tracheoesophageal fistula (EA-TEF) is one of the differential diagnoses for respiratory distress in the newborn. As the esophageal continuity is lacking, the baby is unable to feed and is likely to aspirate; literally drowning in its own saliva. In India, where many babies are born at home and may present late with severe respiratory distress, EA-TEF may be overlooked when the neonate presents with pneumonia. Missing this diagnosis can have grave implications.

#### EPIDEMIOLOGY

Esophageal atresia (EA) has an incidence of 1 in 3,000-4,500 births according to western literature. It is gradually declining, the reasons for which are not yet known. There is no data available citing the incidence of EA-TEF in India. Though the male-to-female ratio is equal in studies from the developed world, several reports from the Indian subcontinent reveal a falsified male preponderance ranging from 65% to 92%. The reason for this skewed ratio can only be attributed to negligence of the girl child by the local population.

#### ETIOPATHOGENESIS

Although a genetic etiology for EA-TEF has not been definitively established, EA-TEF has been known to occur in several generations of the same family with a 2% recurrence risk in the sibling. EA has been known to occur in sets of dizygotic twins. The etiology is most likely heterogeneous and multifactorial and involves multiple genes and complex gene-environmental interactions. The pathogenesis is equally obscure and many theories surround it:

- Esophageal occlusion and failure of recanalization
- Spontaneous deviation of tracheoesophageal septum
- Abnormal migration of putative tracheoesophageal septum
- Mechanical obstruction
- Component of cephalic neurocristopathy
- Defect in signaling pathway of the extracellular organ differentiation-promoting glycoprotein, sonic hedgehog (Shh).

#### ASSOCIATED ANOMALIES

Structural weakness of the membranous part of trachea is commonly associated with EA-TEF resulting in tracheomalacia. This causes the trachea to collapse at the end of expiration simulating stridor, which becomes more obvious when the baby cries. Associated congenital anomalies occur frequently with EA-TEF. Collectively, these anomalies are identified with the acronyms VATER or VACTERL syndrome (when three or more anomalies present), which is seen in 25% of patients with EA-TEF. The various components of VACTERL are as follows: Vertebral (hemivertebrae,

scoliosis, rib deformities); Anorectal malformations (8%); Cardiac defects [ventricular septal defects (VSD), tetralogy of Fallot (ToF), patent ductus arteriosus (PDA), atrial septal defect (ASD), auriculoventricular (AV) defects in 20-40%]; Tracheoesophageal fistula; Renal anomalies (renal agenesis, Potter syndrome, horseshoe kidney, polycystic kidney, urethral atresia, vesicoureteral reflux in 15%); and Limb and radial anomalies (absent radius, radial dysplasia, radial ray deformities, polydactyly, syndactyly and tibial deformities). Coarctation of aorta and single umbilical artery are also known to coexist with EA-TEF. Another acronym for associations is CHARGE that includes Coloboma, Heart defects, Atresia choanae, developmental Retardation, Genital hypoplasia and Ear deformities. Gastrointestinal (GI) tract anomalies (duodenal atresia, ileal atresia, malrotation, Meckel diverticulum), neural tube defects, undescended testes, hypospadias, ambiguous genitalia and trisomy of 13, 21, 18 are found to be associated with EA-TEF.

#### ANATOMIC CLASSIFICATION

The most common anatomic classification used for EA-TEF was suggested by Gross in 1953 and is depicted in **Figures 1A to E**. The most common type, EA with distal TEF (type C) occurs in 75-85% of the cases. The next most frequent is pure EA (type A) seen in 8%; this type is associated with higher incidence of duodenal atresia, Down syndrome and prematurity. Type E (TEF without EA) occurs in 5% cases and is named H-type TEF. Type D (EA with fistula between both proximal and distal ends of the esophagus and trachea) and type B (EA with TEF between proximal segments of esophagus and trachea) are rare.

#### CLINICAL PRESENTATION

The clinical presentation of types A, B, C or D of EA is similar; the neonates present with excessive salivation and drooling. The neonates cough, choke, and get cyanosed when fed. In the presence of distal TEF (EA types C and D), air passes through the fistula into the stomach resulting in abdominal distention. This combined with the chemical pneumonitis that occurs due to regurgitated gastric juice through the distal TEF leads to severe respiratory distress. If EA type C or D is associated with duodenal atresia, the abdominal distention is extreme and occurs very early, mandating urgent surgical correction. In case of EA type A, no air passes into the stomach and the abdomen is rather scaphoid.

#### DIFFERENTIAL DIAGNOSIS

A nasopharyngeal perforation ensuing after traumatic insertion of a nasogastric or orogastric tube is the most important differential diagnosis. The baby has copious oral secretions and the orogastric tube cannot be passed in the stomach. In fact, the orogastric tube may track down through this perforation to varying distances outside the esophagus. This complication can ensue in neonates. It can also happen following a rough finger sweep to clean the neonate's mouth following home delivery conducted by an untrained birth attendant in the rural or suburban set-up. The oral secretions in such a case are blood stained, a feature not often seen

**Figures 1A to E** Anatomical variants of esophageal atresia with or without tracheoesophageal fistula

with a neonate of EA-TEF. In case of doubt, a contrast study could be performed.

## DIAGNOSIS

### Antenatal Diagnosis

Less than 50% of the cases can be diagnosed antenatally. The two often-mentioned signs on ultrasound—presence of polyhydramnios and absent or small stomach bubble—are at best indirect and nonspecific. The visualization of cervical or thoracic fluid image corresponding to the expansion of the bottom of upper esophageal (*pouch sign*) on antenatal ultrasound or MRI is more specific. Recently, amniotic fluid biochemical markers (a biochemical pattern characterized by high total protein,  $\gamma$ -glutamyl transpeptidase and normal L-leucine aminopeptidase) have been suggested to have 100% detection rate.

### Postnatal Diagnosis

An orogastric tube (10Fr red rubber catheter) cannot be passed into the stomach and arrests at 9–11 cm. The *pouch sign* may occasionally be seen on a plain chest radiograph. If a soft infant feeding tube is used, it will be seen coiled in the upper esophageal pouch.

### Plain Radiograph of Chest and Abdomen

The upper pouch can clearly be seen as a blind ending structure with the tube coiled in it. Besides, it is important to determine the

presence or absence of bowel gas in the abdomen as it indicates the nature of fistula, e.g., presence of abundant air shadows in the gastrointestinal tract depicts a distal TEF (**Fig. 2**), gasless abdomen is seen in pure EA (or rarely a tiny distal TEF blocked by a mucous plug) (**Fig. 3**), presence of a double bubble and paucity of distal gas in bowel in addition to EA imply a coexisting duodenal atresia, etc. In addition, there may be associated aspiration pneumonia (commonly seen as consolidation of right upper zone), especially when the baby presents late and is being fed since the diagnosis has been missed at birth. Associated anomalies such as hemivertebrae, cardiomegaly and extra ribs can also be visualized on the plain radiograph.

### Look for Associated Anomalies

*Echocardiography* is necessary to rule out associated anomalies of heart and great vessels. It will also reveal whether the aortic arch is left sided or right sided, which may influence the approach to surgical repair. Vertebral anomalies are evaluated by *plain radiography*; a spinal ultrasound may be done, if any is detected. Perineum must be carefully looked at to rule out associated anorectal malformation. Conversely, in all newborns with anorectal malformation, EA-TEF should be excluded by passing an orogastric red rubber catheter. An associated enlarged kidney (hydronephrosis or multicystic kidney) may be clinically

**Figure 2** Plain radiograph showing blind upper pouch, gas in bowel suggesting distal TEF

**Figure 3** Plain X-ray showing blind upper pouch and gasless abdomen suggestive of pure EA

palpated; this needed to be confirmed on *abdominal ultrasound*. The associated limb deformities, if any, are very obvious, the most common being radial aplasia or hypoplasia (**Fig. 4**). The relevant plain radiographs would confirm these. Rib anomalies may also be present. Presence of 13th rib on one or both sides suggests presence of longer gap between the upper and lower esophageal segments. Presence of a booming cough with or without inspiratory stridor may indicate concomitant tracheomalacia.

### Upper Gastrointestinal (GI) Contrast Study

Water soluble contrast study should be done with extreme caution to avoid aspiration pneumonitis, only when the diagnosis cannot be confirmed on clinical or plain radiological imaging, e.g., late presentation around 10 days of life, suspicion of cricopharyngeal perforation (**Fig. 5**).

## MANAGEMENT

### Initial Resuscitation

The initial resuscitation of neonates with EA-TEF includes initiation of warmed electrolyte solution, intravenous antibiotic therapy, decompression of the upper pouch and other maneuvers to improve the respiratory status. Two strategies are devised to

decrease the degree of aspiration of saliva pooling in the upper esophageal pouch: (i) to nurse in the anti-Trendelenburg position, (ii) a sump catheter (Replegle tube) is placed in the upper pouch on continuous suction. If Replegle tube is unavailable, frequent low pressure suctioning is mandated.

### Risk Stratification

There are several risk stratification systems described like Waterston and Spitz criteria, which are based on the birthweight, presence of and severity of pneumonia and presence and type of associated other congenital anomalies with special attention to congenital heart disease. Presence of life-threatening cardiac anomaly takes precedence over EA-TEF repair and presence of pneumonia may mandate few days of antibiotics and even ventilation before definitive surgical repair.

### Timing of Surgical Intervention

In a stable neonate, the definitive repair may be performed soon after the work-up for the associated anomalies is done. Definitive repair of the EA-TEF is rarely a surgical emergency to be performed in the middle of the night.

### Management in the Preterm Neonate

A premature neonate with EA-TEF has the following issues that deteriorate his pulmonary status associated hyaline membrane disease; recurrent aspiration through the fistula; increased abdominal distention, which leads to raised diaphragm, basal atelectasis and compromised lung expansion. Such a preterm neonate would be better off with high frequency oscillatory ventilation (HFOV). Severe gastric distention may mandate placement of a gastrostomy tube. However, once the gastrostomy tube is placed, the pulmonary status could paradoxically worsen as the ventilated gas preferentially may pass through the TEF and get lost through gastrostomy. To correct this problem, the gastrostomy tube may be placed under water seal. The definitive repair would be done only after alleviation of the pulmonary status of the neonate.

### Primary Esophageal Anastomosis

In a stable infant, division of TEF and primary esophageal repair is done. Preoperative bronchoscopy may be performed to determine the opening of the distal esophageal segment in trachea, carina or right bronchus. A retropleural approach is preferred over the transpleural approach for repair. A primary esophagoesophageal anastomosis is performed over a transanastomotic feeding tube. A chest tube drain is placed and the incision is closed. With the advent of minimally invasive surgery, thoracoscopic repair of EA-TEF is also being done in stable patients.

### Postoperative Management

Routine postoperative intubation and ventilation is undesirable as it may put pressure on the site of tracheal closure. However, postoperative ventilation would be mandatory in the presence of prematurity or pneumonia. Whenever, the anastomosis is performed under some tension, it is preferable to electively ventilate the neonate for 3–5 days even, if pulmonary status is satisfactory.

If a transanastomotic tube is placed, expressed breastmilk could be fed through it from the very early postoperative period. In case transanastomotic tube is not placed, then parenteral nutrition would need to be instituted through a central line. The chest tube drain should not drain more than few mL of serous fluid on 1st postoperative day in the normal course; presence of saliva in the tube indicates an anastomotic leak. A contrast swallow is obtained on 7–10th postoperative day to determine whether a leak is present and to rule out anastomotic stenosis, if any. If no

**Figure 4** Plain radiograph of a neonate with esophageal atresia (EA) type C with associated vertebral defects, scoliosis, radial aplasia and right upper zone consolidation

**Figure 5** Contrast study showing nasopharyngeal perforation that was clinically mimicking as EA-TEF

**Figure 6** Contrast dye study demonstrating recurrent TEF

leak is demonstrable, the chest tube and the nasogastric tube are removed and the breastfeeding is started.

## COMPLICATIONS

### Early Complications

These include an anastomotic leak (10–15%), anastomotic stricture (10–20%) and recurrent TEF (5–15%). All three complications may coexist in a particular patient. *Major anastomotic leaks* manifest within first few postoperative days with hydropneumothorax, mediastinitis and sepsis and necessitate immediate surgical exploration. *Minor anastomotic leak* is usually incidentally detected on the contrast swallow or may be seen in the form of small amount of saliva in the chest tube in a stable neonate. It invariably heals spontaneously.

*Strictures* may present with swallowing difficulties (dysphagia, vomiting, cough, poor or slow feeding), foreign body obstruction (including food bolus), recurrent respiratory tract infections and/or poor weight gain. Diagnosis is made on barium esophagography and esophagoscopy. Few dilations with Savary-Gilliard bougies are usually required. Rarely, resection of the stricture and repeat anastomosis are necessitated.

The diagnosis of *recurrent TEF* would warrant barium esophagography and bronchoscopy (**Fig. 6**). Reoperation would be indicated in most of the cases, though there are some reports of success with endoscopic use of laser, cautery, tissue adhesives or biological mesh.

### Late Complications

These include gastroesophageal reflux (GER), esophageal dysmotility and tracheomalacia. Varying degrees of *gastroesophageal reflux* occur in almost neonates after repair of EA-TEF. Nearly two-thirds of EA patients have some form of *dysphagia* in adulthood.

*Tracheomalacia* tends to improve with growth of the baby, but severe and persistent tracheomalacia may require aortopexy.

## SPECIAL CIRCUMSTANCES

Patients with type *E TEFs*, also called *H-type*, usually present beyond the newborn period. Recurrent chest infections and failure to thrive are the common presentations. The diagnosis of H-type TEF is often made on barium esophagography and is confirmed on bronchoscopy. Division of the H-type fistula is generally possible through a cervical approach; a thoracotomy is rarely necessitated. The outcome is invariably good. Neonates born with *EA-TEF and duodenal atresia* require an urgent surgical treatment owing to the closed obstruction of the stomach and proximal duodenum; any delay may lead to gastric perforation.

*Pure EA* (type A) represents a difficult entity to treat as primary esophageal anastomosis is usually not feasible owing to the fact that the upper and lower ends are too apart. Traditionally, the treatment approaches include performing a feeding gastrostomy tube at presentation, bouginage over weeks and months to lengthen the upper pouch and then doing delayed primary esophageal anastomosis. Reconstruction in the form of esophageal replacement is required using either a gastric pull-up or gastric tube or colon interposition. Foker's technique has been described for pure EA and other long-gap EA in recent years.

## OUTCOME AND PROGNOSTIC FACTORS

Many different risk stratification or prognostication systems have been used (**Table 1**). Antenatal diagnoses of EA have been known to be associated with a 75% mortality rate. In the low-risk neonates, the overall survival rates of greater than 90% have been achieved in the western world. In high-risk neonates (those having

**Table 1** Risk stratification systems for EA-TEF

Waterston (1962)		Montreal (1993)		Spitz (1994)	
<b>A</b> (mortality 0%)	Birthweight > 2,500 g, well	<b>I</b> (mortality 7.3%)	All other patients	<b>I</b> (mortality 3%)	Birthweight ≥ 1,500 g and no major cardiac anomaly
<b>B</b> (mortality 4%)	Birthweight 1,800–2,500 g and well Or Birthweight > 2,500 g and moderate pneumonia or congenital anomaly	<b>II</b> (mortality 69.2%)	Life-threatening anomalies  Both major anomalies and ventilator dependence	<b>II</b> (mortality 41%)	Birthweight < 1,500 g or major cardiac anomaly
<b>C</b> (mortality 11%)	Birthweight < 1,800 and well Or Birthweight > 2,500 g and severe pneumonia or congenital anomaly			<b>III</b> (mortality 78%)	Birthweight < 1,500 g and major cardiac anomaly

associated severe cardiac and chromosomal anomalies or extreme prematurity), the survival rates have been quoted in the range of 50%. Staged procedures have increased survival rates in these high-risk neonates. Despite such remarkable survival figures in these western centers, nearly half of the survivors have complications. Data from the Indian subcontinent show an overall survival rate of 40–55% with only 20–30% survival in high-risk groups, though there are no recent statistics available. Reports from Africa paint a much more dismal picture.

### IN A NUTSHELL

1. Esophageal atresia with or without fistula is not a surgical emergency.
2. Preoperative stabilization and assessment for associated anomalies should be done before surgical correction.
3. Prognostic risk stratification is helpful in decision making.
4. Native esophagus is the best esophagus; hence, all attempts should be made to achieve a primary anastomosis.
5. In high-risk patients with long gap or pure EA (without fistula), diversion in the form of cervical esophagostomy and gastrostomy is a feasible option.
6. Developing countries lag far behind in providing good survival rates for EA-TEF due to lack of infrastructure and neonatal supportive care.
7. Close follow-up for detecting early and/or late complications is advisable.

## Chapter 18.2

# Diaphragmatic Hernia and Eventration

*Shalini Sinha, Yogesh Kumar Sarin*

Malformations of the diaphragm in the newborn include congenital diaphragmatic hernia (CDH) and eventration of diaphragm (ED). While CDH is a life-threatening anomaly that can easily be diagnosed prenatally, ED usually presents beyond the neonatal age and sometimes even in adulthood. The physiological derangements associated with CDH in the form of pulmonary hypoplasia and pulmonary hypertension [persistent pulmonary hypertension of the newborn (PPHN)] need expert management by skilled neonatologists both before and after surgery.

### EPIDEMIOLOGY

Congenital diaphragmatic hernia occurs in approximately 1 in every 2,000 to 4,000 newborns. There is no data available from developing countries. About one-third neonates may be stillborn and hence the calculation of its incidence is likely to be underestimated. In 80–85% patients, the CDH is left-sided. A hernial sac is seen in 10–15% of CDH cases.

### ETIOLOGY

The exact etiology of CDH is still unknown. It is believed to be multifactorial with interplay of genetic as well as environmental factors. The fetal diaphragm develops in 7–10th week of gestation by fusion of the pleuroperitoneal membranes with the septum transversum and dorsal mesentery of the esophagus thus closing the pleuroperitoneal canal. Any interference in this process results in CDH. The nitrofen model speculates that CDH is an embryopathy caused by toxin exposure in early gestation. The role of retinoic-acid-related target gene in the causation of CDH is also being studied.

### PATHOGENESIS

Herniation of abdominal viscera into the thoracic cavity in CDH hinders the growth of the ipsilateral lung. The heart and mediastinum are shifted to the opposite side thus compressing the contralateral lung. Diminished intrathoracic space affects the pseudoglandular phase of lung development during the first trimester and results in bilateral pulmonary hypoplasia, which is more severe on the ipsilateral side. There is inadequate surface area for gas exchange, decreased cross-sectional area of the pulmonary vascular tree, precocious muscularization of the pulmonary vessels and probable surfactant deficiency. Raised levels of circulating vasoactive mediators, along with an increased sensitivity to these mediators, further accentuate the pulmonary hypertension.

With the initiation of the newborn's first breath, fetal circulation is converted to the adult type due to fall in pulmonary vascular resistance. Failure of this process, as occurs in CDH patients, leads to persistent fetal circulation with increased right to left shunt, either at atrial or ductal level. This causes fall in the saturation of systemic blood circulation and hypoxia, which further increases the pulmonary vascular resistance. A vicious cycle develops which results in respiratory failure.

The abdominal viscera that herniate through the diaphragmatic defect on the left side include left lobe of liver, spleen, stomach, varying lengths of small and large intestine and rarely left kidney. There may be an obstruction at the level of gastroesophageal junction due to displacement of the stomach, thus resulting in

polyhydramnios. On the right side, the right lobe of liver along with intestines occupy the hemithorax. Abnormal drainage of the hepatic veins directly into the right atrium may cause difficulty in surgical repair. When a sac is present, it is formed by the parietal pleura and peritoneum.

### Anatomic Classification

Bochdalek hernia is a posterolateral defect in the embryogenesis of the diaphragm and is the most common type of CDH constituting 95% of cases. Morgagni hernia is a rare anterior defect in the diaphragm and forms 2% of CDH patients. Also known as parasternal or retrosternal hernia, the abdominal contents herniate through the foramen of Morgagni, which lies adjacent to the xiphoid process of the sternum.

### CLINICAL PRESENTATION

The presentation of a baby born with CDH depends on the degree of pulmonary hypoplasia and associated PPHN. The spectrum of severity includes an infant with severe pulmonary hypoplasia and hypoxemia refractory to conventional and innovative ventilation techniques to those with a much more benign course and minimal blood gas derangements. Most patients develop respiratory distress either at birth or within the first 24 hour of life. Milder forms may present by 5–7 days. In developing countries, where antenatal pick-up is poor and many babies are born at home, only the milder forms of CDH reach hospital in time for intervention. Since the pulmonary hypertension is less in those with delayed presentation, the salvage rates are better. Rarely, a small group of cases goes unrecognized into adulthood.

Other presentations of CDH in the newborn include antenatally diagnosed CDH; respiratory distress at birth associated with cyanosis, hypoxia, tachycardia; abnormal bulge of hemithorax on the affected side; mediastinal shift to opposite side as seen by abnormal position of the cardiac impulse; bowel sounds heard over the hemithorax instead of breath sounds or a scaphoid abdomen. A neonate with Morgagni hernia or right-sided Bochdalek hernia may not be symptomatic at birth and may present later with respiratory or gastrointestinal symptoms.

### Associated Anomalies

Other anomalies are present in about 40% cases, most commonly congenital heart disease. Nearly 20% are found to have genetic defects. The various anomalies associated with CDH include neural tube defects, cranial malformations, hypoplastic left heart syndrome, tetralogy of Fallot, and coarctation of aorta and skeletal anomalies. Nonrotation of gut is almost invariably present. Tracheobronchial tree anomalies—tracheal stenosis, trifurcation of trachea are seen in 18% cases. Stillborn infants with CDH have a very high incidence of associated lethal anomalies nearing 100%.

### DIFFERENTIAL DIAGNOSIS

Congenital cystic lesions of the lung may simulate the presentation of CDH. These babies may also have respiratory distress at birth and a macrocystic variety of congenital cystic adenomatoid malformation (CCAM) may mimic the X-ray picture of CDH. When in doubt, a simple method to differentiate the two entities is to repeat the X-ray after inserting a nasogastric tube. This will confirm the presence of the stomach in the hemithorax in CDH. In a stable neonate, computed tomography can help. Rarely, agenesis of lung can be confused with CDH. A Bochdalek hernia may have a similar picture on chest X-ray as Morgagni hernia or congenital hiatus hernia which can be differentiated on upper GI contrast study. The radiological picture of CDH with sac simulates that of ED. The latter can be confirmed by paradoxical movements of the diaphragm as seen on fluoroscopy.

## DIAGNOSIS

### Antenatal Diagnosis

#### Prenatal Ultrasonography

The presence of stomach bubble or fluid-filled intestinal loops in the fetal hemithorax at the same cross-sectional level as the heart is suggestive of CDH on antenatal sonography (**Fig. 1**). Mediastinal shift to the opposite side, absence of stomach bubble in the abdomen and presence of liver in the thorax may also help in diagnosing CDH prenatally. Associated polyhydramnios is seen in about 80% cases. These features may be evident around 18 weeks of gestation at the time of level II scan, however, the mean age of antenatal detection of CDH has been reported to be around 24 weeks with a diagnostic accuracy of 40–90% as per western literature. Other associated anomalies should also be looked for lung to head ratio (LHR) and lung-thoracic ratio (LTR) have been used as prognostic markers. **Table 1** summarizes the prenatal ultrasound findings in CDH.

#### Others

*Fetal echo* is done to confirm and evaluate the details of concurrent heart disease. *Three-dimensional ultrasound* has been used to confirm the antenatal diagnosis and accurately assess the perinatal outcome. *Fetal MRI* is increasingly being used for detailed quantitative assessment of complex congenital anomalies including CDH. It is also useful to calculate lung volumes and reliably assess the degree of liver herniation.

### Postnatal Diagnosis

*Plain radiograph of chest and abdomen* shows absence of diaphragmatic dome on the affected side with herniation of bowel loops into the hemithorax in addition to the mediastinal shift (**Fig. 2**). Postnatal echocardiography is indicated for associated heart anomalies and to detect PPHN. Measurement of *preductal arterial blood gas (ABG)* is a cornerstone for attempting to establish clinical predictive criteria in CDH. The newborn is considered stable, if the  $\text{PaO}_2$  is greater than 100 mm Hg and  $\text{PCO}_2$  is less than 50 mm Hg. The diagnosis of PPHN in CDH is usually made on the basis of a preductal or postductal saturation gradient. *Upper GI contrast study* may be useful in Morgagni hernia when there is intermittent herniation of bowel and a normal X-ray appearance.

## MANAGEMENT

Medical therapy of CDH entails optimizing oxygenation while avoiding barotrauma, using gentle ventilation and permissive hypercarbia. Newer modalities such as high-frequency oscillatory ventilation (HFOV), intratracheal pulmonary ventilation (ITPV), inhaled nitric oxide (iNO) and extracorporeal membrane oxygenator (ECMO) can be used in severe cases; however, they have not been shown to clearly improve the outcome. The available evidence suggests that outcomes are better when infants with CDH are delivered at experienced centers, the surgical repair is delayed until hemodynamic and respiratory stability is achieved, and by the use of nonaggressive mechanical ventilation and permissive hypercapnia.

### Perinatal Stabilization

The indications for fetal stabilization are LTR of less than 0.2 in the absence of any severe associated anomalies in a near term fetus of at least 36 weeks gestation. The protocol for fetal stabilization includes:

- Monitoring of fetal respiratory movement and heart beat by ultrasonography
- Administration of morphine (20–30 mg) and diazepam (5 mg) to the mother

**Figure 1** Prenatal ultrasonogram at 24 weeks gestation and stomach fundic bubble (FB) at the same cross-sectional level as the heart (HRT) suggestive of congenital diaphragmatic hernia

**Table 1** Features described in literature on antenatal ultrasonography in fetus with congenital diaphragmatic hernia

1. Major mediastinal shift
2. Intrathoracic stomach/bowel/liver
3. Polyhydramnios
4. Reduced fetal abdominal circumference
5. Fetal pulmonary artery diameters on Doppler US
6. Fetal LHR (LHR of < 1.0 suggests bad prognosis)
7. LTR (LTR of < 0.2 suggests bad prognosis)
8. Nakata index: Right lung area/thorax area ratio (< 0.11 suggests bad prognosis)
9. Fetal lung volume on 3D US
10. Fetal nuchal translucency thickness (as a marker of intrathoracic compression-related pulmonary hypoplasia)
11. Associated anomalies

Abbreviations: LHR, lung-head ratio; LTR, lung-thoracic ratio.

**Figure 2** Chest radiograph showing herniation of bowel loops into the left hemithorax and mediastinal shift to right, suggestive of left-sided congenital diaphragmatic hernia

- Confirmation of any interruptions in fetal movement followed by a cesarean section
- Administration of muscle relaxant pancuronium (0.5 mg) through the umbilical vessels
- Intubation before clamping of the umbilical cord
- HFOV without bagging.
- Perinatal stabilization has been found to be effective in preventing PPHN, improving the survival rate of patients with severe CDH.

### Postnatal Resuscitation

A neonate with suspected or confirmed diagnosis of CDH must be delivered at a tertiary care center where facilities for HFOV, ITPV, iNO, ECMO, etc. are readily available and neonatal surgical expertise is at hand. Due to cardiorespiratory instability, transfer of these patients is extremely precarious and should be avoided. Delivery should be planned at term; a prenatal diagnosis of CDH alone is not an indication for cesarean section. Bag and mask ventilation is contraindicated during resuscitation of the neonate as it can distend the stomach and intestines with air and thus worsen the respiratory compromise. The newborn should be immediately intubated in the delivery room. Decompression of the stomach by placement of a nasogastric tube and aspiration is extremely helpful. The baby should then be shifted to the neonatal intensive care unit (NICU) for placement of arterial and venous access through the umbilicus, and baseline investigations including preductal ABG, chest X-ray, echocardiography should be sent. A transcutaneous saturation probe should be placed on the right upper limb to record the preductal saturation ( $\text{SpO}_2$ ). As for all neonates, meticulous attention should be paid to thermoregulation, glucose homeostasis and hemodynamic circulation. Avoidance of any stressful stimuli which can exacerbate PPHN is important. Different ventilator modalities should be tried to maintain a  $\text{PaO}_2$  of greater than 85 mm Hg. The surgeons should be informed about the admission of such a neonate in the NICU so that they can coordinate with the neonatologist regarding the optimal time for surgery.

### Timing of Surgery

Controversy still exists regarding the best time for surgical intervention in CDH. The possibilities are:

- In utero
- Emergent (within 2–4 hours after birth or arrival of the patient in our context)
- Urgent (within 24 hours of birth or arrival)
- Delayed (not related to any particular time cut-off; instead it is a delayed primary repair done after physiological stabilization of the neonate)

A Cochrane analysis published in 2002 could not delineate any substantial advantage of delayed repair over an urgent surgical correction of CDH.

*Fetal surgery* is promising as it may help to ameliorate the progression of PPHN in the fetus. However, it is plagued with a high incidence of preterm labor and fetal loss. In addition, it has not shown an improved outcome. The plug the lung until it grows (PLUG) and fetal endoscopic tracheal occlusion (FETENDO) techniques are minimally invasive alternatives to fetal surgery; however, even they have failed to show any improvement in outcome.

### Ventilatory Stabilization and Treatment of Persistent Pulmonary Hypertension of the Newborn

Modes of ventilation used in CDH are summarized in **Table 2**. Increased pulmonary vascular resistance is an almost universal

finding in CDH even when not clinically manifest by right-to-left shunting at the ductal level. The diagnosis of PPHN in CDH is usually made on the basis of a preductal or postductal saturation gradient. There are three distinct groups into which these very newborns with CDH can be categorized: (i) minimal pulmonary hypoplasia, (ii) unilateral hypoplasia and (iii) bilateral hypoplasia. The first group probably does not need pharmacologic support, while in the last, it probably does not help. Management of PPHN has been already discussed in a previous chapter.

Key aspects of management are outlined in **Box 1**.

#### BOX 1 Key aspects of management of CDH

- *In utero* referral of prenatally diagnosed CDH to experienced center with advanced neonatal intensive care facilities
- Planned delivery at term
- No bag and mask ventilation
- Immediate intubation of the newborn in the delivery room
- Nasogastric tube placement and frequent aspiration of gastric contents and air
- Shifting to the NICU for respiratory and hemodynamic stabilization after baseline investigations
- Gentle ventilation and permissive hypercapnia
- Delayed surgical intervention after physiological stabilization
- CDH is a physiological emergency and not a surgical emergency.

### The Operative Technique

#### Surgery

Details of surgical technique are beyond the purview of this chapter. Minimally invasive techniques such as laparoscopic or thoracoscopic repair of CDH are best suited for delayed presentation in stable neonates.

#### Postoperative Care

The preoperative and perioperative resuscitation measures are continued in the postoperative period. Enteral feedings are started when nasogastric aspirates decrease. Drain can be removed when it stops functioning and there is no hemo- or pneumothorax on chest X-ray.

#### Neonatal Lung Transplantation

One of the several innovative therapies that have been described for high-risk CDH include lung transplantation. This option is often discussed as a potential solution and has some experimental support. The clinical experience has been limited to few patients of CDH.

### COMPLICATIONS

Recurrence of CDH is seen in 10–50% of cases with agenesis of diaphragm requiring prosthetic patches and is difficult to manage surgically. Long-term complications such as failure to thrive, chronic pulmonary disease, neurodevelopmental delay, esophageal dysmotility and reflux are seen in half the patients ever since the survival of neonatal CDH has improved. Although alveolar growth is known to occur till 8 years of age, these children have emphysematous lungs and may develop a bronchopulmonary dysplasia like picture.

### OUTCOME AND PROGNOSTIC FACTORS

The mortality rate associated with CDH remains high all over the world (30–70%) despite great advancements in biotechnology. Survival is dismal in developing countries lacking infrastructure. In a recent study by diaphragmatic hernia research and

**Table 2** Different modes of ventilation used in congenital diaphragmatic hernia

Mode of ventilation	Characteristics	Advantages	Disadvantages
CMV	High PIP $\leq 25$ cm H <sub>2</sub> O, high rates, target PaO <sub>2</sub> of $>85\%$	Simple routine principles of ventilation, can be done in smaller set-ups	High PIP associated with VILI-barotrauma, pneumothorax and BPD
Permissive hypercapnia	Maintain PaCO <sub>2</sub> of 40–50 mm Hg	Less VILI	Respiratory acidosis
HFOV	Oscillations at a frequency of 3–15 Hz	Maintains PEEP without VILI	Needs specialized equipment
ITPV	Constant flow of humidified gas through reverse Venturi catheter kept at distal end of the endotracheal tube	Reduces physiological dead space, facilitates expiration and improves elimination of CO <sub>2</sub>	Needs specialized equipment
iNO	Used in conjunction with HFOV	Vasodilator for pulmonary vasculature	May not be available in smaller set-ups
Liquid ventilation	Perfluorocarbons-inert liquids with low surface tension and high solubility for respiratory gases (administered daily; total cumulative doses of $36 \pm 8$ mL/kg over 5–6 days)	Used in conjunction with HFOV, iNO	May not be available in smaller set-ups
ECMO	VA or VV bypass	Used when no response to all other modes	Hemorrhagic complications, provides short-term support
Surfactant	Not useful in CDH		

*Abbreviations:* CMV, conventional mechanical ventilation; HFOV, high frequency oscillatory ventilation; ITPV, intratracheal pulmonary ventilation; iNO, inhaled nitric oxide; ECMO, extracorporeal membrane oxygenation; PIP, peak inspiratory pressure; VILI, ventilator induced lung injury; VA, venoarterial; VV, venovenal; PEEP, positive end expiratory pressure; BPD, bronchopulmonary dysplasia.

exploration; advancing molecular science (DHREAMS) group, it was found that survivors of CDH had lower developmental scores at age of 2 years. Factors associated with developmental delays were need for ECMO, supplemental oxygen at 28 days of life, discharge on enteral tube feeds, need for readmission and lower socioeconomic status.

Poor prognostic factors for survival in CDH are listed in **Box 2**. PPHN is the most challenging factor that ultimately determines the final outcome. In a developing country like ours, an antenatal diagnosis may not be available in many and the neonate may arrive after few hours or days of birth with respiratory distress. There is a need for stratification of risk to decide the management strategy. These neonates can be broadly divided into three groups:

**Group 1** Neonates who present later than 6 hour of birth are relatively stable. They can be taken up for an urgent surgery after about 4 hour of arrival following confirmation of diagnosis and initial resuscitation and investigations. The survival rates are usually good.

**Group 2** Includes physiologically unstable patients as per criteria described in **Table 3**. They require postnatal resuscitation and

stabilization over few days before they can be taken up for surgical repair safely.

**Group 3** Those with very severe pulmonary hypoplasia who do not stabilize despite of all measures including ECMO. To decide timing about surgical repair in this group of patients is extremely difficult as they shall never stabilize. These patients may be either left alone or operated when the treating physicians believe that there is no further chance of improvement. Survival rates are poor.

### Honeymoon Period

Honeymoon period in the context of neonatal CDH refers to a transient stable interval during which adequate oxygenation (PaO<sub>2</sub>  $> 100$  mm Hg + PCO<sub>2</sub>  $< 50$  mm Hg) is maintained with maximal conventional ventilatory and supportive therapy. This phenomenon is usually seen in first 48 hours of life and has been

**Table 3** Postnatal predictors of outcome of CDH

X-ray assessment of contralateral lung
Blood gas derangement (initial blood gases and in relationship to maximal ventilatory settings)
Initial PaO <sub>2</sub> and PaCO <sub>2</sub> , pH, best postductal PaO <sub>2</sub> and worst: PaCO <sub>2</sub> after 6 hours of treatment, best PaCO <sub>2</sub> after 48 hours of treatment, $VI=RR \times MAP \times PaCO_2$ , $MVI=RR \times PIP \times PaCO_2/1,000$
Indices of cardiopulmonary stability/pulmonary hypertension: $V_t$ , pulmonary compliance/CRS, dynamic compliance, CO <sub>2</sub> index, A-aDO <sub>2</sub> , OI, Bohn's criteria (four quadrants), MGI (ratio between diameters of pulmonary arteries and descending aorta), MGI and birthweight. (four categories)
Other criteria: Prenatal diagnosis, associated anomalies especially, cardiac defects, prematurity, low birthweight, major air leak, Apgar scores at 1 and 5 min, lack of honeymoon period (continued low PaO <sub>2</sub> )

*Abbreviations:* VI, ventilation index; RR, respiratory rate; MVI, modified ventilation index; MAP, mean airway pressure; PIP, peak inspiratory pressure;  $V_t$ , initial tidal volume; CRS, compliance of respiratory system; A-aDO<sub>2</sub>, alveolar-arterial difference; OI, oxygenation index; MGI, McGoon index.

#### BOX 2 Poor prognostic factors for survival in CDH

- Prenatal diagnosis before 25 weeks of gestation
- Coexisting severe congenital heart disease or other major associated anomalies
- Fetal LHR less than 1.0
- Fetal LTR less than 0.2
- Nakata index: Right lung area/thorax area ratio less than 0.11
- Presence of polyhydramnios\*
- Diaphragmatic agenesis requiring prosthetic mesh
- Herniation of stomach into the hemithorax\*
- Right-sided CDH\*
- Severe pulmonary hypertension at 1 month of age
- Prematurity
- Low birthweight
- Need for ECMO.

\*Equivocal studies, hence role not confirmed.

known to last for about 24 hours after which the subjects deteriorate because of PPHN and left to right shunting. The honeymoon group of patients has a lesser degree of pulmonary hypoplasia and is known to have better outcome than the no-honeymoon group of neonates who have overwhelming pulmonary hypoplasia.

### FORAMEN OF MORGAGNI HERNIA

Morgagni hernia occurs through a diaphragmatic defect in the anteromedial part. It usually presents in older children with an acute gastrointestinal crisis due to strangulation of the herniated colon and small intestine through the narrow defect. Rarely, it can be seen in neonates as an incidental finding on chest radiograph—air-fluid levels or as a mediastinal mass. A sac is almost always present and there is no pulmonary hypoplasia or PPHN associated. There may be nonrotation of gut. Rarely, it is seen as a part of Cantrell's pentalogy with several other midline defects. A GI contrast study or computed tomography can confirm the diagnosis. Operative correction can be performed through the abdominal route by reducing the contents and repairing the defect. Thoracoscopic and laparoscopic approaches are also useful as these children are much older and usually stable.

### EVENTRATION OF DIAPHRAGM

Congenital ED may present analogous to neonatal CDH with sac. More commonly, infants with ED become symptomatic beyond the neonatal period with recurrent lower respiratory tract infections and episodic respiratory distress. The diaphragmatic muscle though completely present is atretic and fibrosed, hence remains elevated into the thorax. Acquired ED occurs due to phrenic nerve injury either during birth (Erb's palsy) or following surgical correction of congenital heart disease. Eventration can either be partial or complete, left sided or right sided.

The patient may be absolutely asymptomatic and the finding of elevated dome of diaphragm on X-ray may be incidental (**Fig. 3**). Diagnosis of ED is confirmed by visualization of paradoxical movements on fluoroscopy due to phrenic nerve paralysis. Computed tomography can also help when in doubt.

A small ED can be left alone in an asymptomatic patient unless there is atelectasis of the ipsilateral lung compromising its growth.

**Figure 3** Chest radiograph showing elevated left hemidiaphragm suggestive of eventration of diaphragm (ED)

A large ED or a symptomatic one needs surgical intervention in the form of plication with nonabsorbable sutures. Right-sided ED is better accessed by thoracotomy whereas left-sided repair of ED is preferred via abdominal route. In the neonate having respiratory distress, the differentiation between CDH with sac and ED is often made intraoperatively. Thoracoscopic and laparoscopic methods of plication can also be done in stable patients. The prognosis of infants with ED is much better than CDH.

### IN A NUTSHELL

1. CDH is a medical emergency and not a surgical emergency. Surgery should be done after physiological stabilization of the neonate.
2. PPHN associated with CDH need expert management by skilled neonatologists both before and after surgery.
3. Prenatal diagnosis can be made in 40–90% cases in the west, thus facilitating referral to specialized tertiary centers. Characteristic feature on ultrasonography is the detection of heart and stomach at the same cross-sectional level.
4. Respiratory distress at birth associated with abnormal bulge of hemithorax, mediastinal shift to opposite side and scaphoid abdomen are suggestive of a diagnosis of CDH.
5. Preductal ABG is the cornerstone for establishing clinical predictive criteria in CDH. The newborn is considered stable, if the PaO<sub>2</sub> greater than 100 mm Hg and PCO<sub>2</sub> less than 50 mm Hg.
6. Despite availability of advanced methods of ventilation and pharmacological support, the best mode of treatment and the ideal timing of surgery still remain elusive.
7. Medical therapy of CDH entails optimizing oxygenation while avoiding barotrauma, using gentle ventilation and permissive hypercarbia.
8. Prenatal diagnosis before 25 weeks of gestational, coexisting severe congenital heart disease and fetal LHR less than 1.0 on the antenatal ultrasound are some of the poor prognostic factors.
9. The mortality rate remains high all over the world (30–70%) despite all efforts. Survival is dismal in developing countries lacking in infrastructure.
10. Delayed presentation of milder forms of pulmonary hypoplasia has better outcomes.

## Chapter 18.3

# Gastrointestinal and Abdominal Malformations

Satish Kumar Aggarwal

### NEONATAL INTESTINAL OBSTRUCTION

Common gastrointestinal (GI) malformations relate to congenital mechanical obstruction, such as atresia or stenosis, functional obstruction such as Hirschsprung disease (HD) or abnormality of bowel rotation and fixation referred to as malrotation. The causes of neonatal intestinal obstruction are listed in **Box 1**.

#### BOX 1 Congenital intestinal malformations leading to neonatal intestinal obstruction

- Esophageal atresia
- Pyloric atresia (uncommon)
- Duodenal atresia
- Jejunal atresia
- Ileal atresia
- Colonic atresia
- Rectal atresia (uncommon)
- Anorectal malformations
- Meconium disease of infancy
  - Meconium ileus (simple meconium disease)
  - Meconium peritonitis (complicated meconium disease)
- Hirschsprung disease (functional obstruction)
- Congenital hypertrophic pyloric stenosis (onset at 3–4 weeks).

### General Clinical Aspects

Bile-stained vomiting and abdominal distension are the key features of neonatal intestinal obstruction. Timing and degree of abdominal distension vary depending on the level of obstruction. Abdominal distension is directly related to the amount of gas in the gut. At birth, there is no gas in the intestines. With the onset of breathing, some air gets ingested leading to normal distribution of bowel gas soon after birth. Proximal obstructions, such as duodenal and jejunal atresia, present with early vomiting but minimal distension. Distension at birth has limited differential diagnosis: congenital mass lesions (duplications, lymphangioma, retroperitoneal teratoma) and meconium disease of infancy especially giant cystic meconium peritonitis. Ileal and colonic atresia present with gradual distension over 1–2 days and late onset of vomiting.

Most babies born with congenital mechanical bowel obstruction are otherwise well and active. They also accept first few feeds well only to develop vomiting and abdominal distension later. A septic and ill child may develop paralytic intestinal obstruction but in that case the systemic signs will precede intestinal symptom. This may occur in a setting of meconium-stained liquor, premature rupture of membranes, maternal infections and prolonged labor. If a child has passed milk stools, it rules out intestinal atresia.

A baby, who was born normal and healthy and took feeds well but develops bilious vomiting on the 3rd or 4th day and becomes limp and pale suddenly, is most likely to have acute midgut volvulus because of malrotation. Examination will reveal shock and pallor with minimal abdominal signs. Plain abdominal film may show paucity of distal gas with few proximal loops. It may even be normal. This is the most feared entity and although an upper GI contrast study is indicated, there may not be enough time. It is

a fire brigade emergency, requires quick fluid resuscitation and a prompt laparotomy to de-twist the small bowel. Laparotomy may be a part of resuscitation. Failure to act quickly may result in ischemic loss of the entire small bowel with dreaded consequences of short bowel syndrome.

### Imaging

Plain X-ray of the abdomen is the most important imaging tool. An anteroposterior (AP) view should be taken in supine position. Erect view and invertogram are unnecessary and distressing to the neonate. Presence of gas in rectum rules out proximal atresia. Stenosis, however, still remains a possibility. Following diagnoses are possible on plain film:

- Only distended stomach and no distal gas: *Pyloric atresia*
- Distended stomach and proximal duodenum (double bubble) (**Fig. 1**): *Duodenal atresia*. The dimple in between two bubbles is because of the pyloric contraction.
- Proximal few bowel loops seen and no distal loops: *Jejunal atresia*.
- Many distended loops suggest distal obstruction:
  - Many distended loops. Step ladder pattern, many levels on lateral view: *Ileal atresia*
  - Dilated proximal loops, soap bubble appearance and paucity of distal gas: *Meconium ileus*
  - Too many dilated loops with distended abdomen and gas filled loops reaching the periphery: *Hirschsprung disease (HD) or colonic atresia*
  - Calcification on plain film *Meconium ileus (MI) with calcification*. An ultrasound should also be done to look for other causes of calcification such as adrenal calcification, neuroblastoma and teratomas.

### Free Gas on Supine Film

X-ray in an erect position is not necessary to diagnose free gas. Free gas on supine film is seen as *football sign*. The free gas collects in the central abdomen on either side of the falciform ligament, which shows as an oblique shadow in the center of a big blob of gas. Small amount of free gas may be missed on supine film. For this cross table, view in left lateral decubitus position is better. The child lies in lateral position on his left side, X-ray plate is kept against the back and the X-ray beam comes from the front. Small triangular pockets of free air are seen opposite the abdominal wall flanked by bowel loops. Free air may also be seen between the right edge of the liver and the right lateral abdominal wall.

**Figure 1** Plain X-ray in duodenal atresia showing double bubble

### Cross Table Lateral View in Prone Position

The child lies in prone position for 2–3 min with the pelvis elevated by 45° on a soft wedge. X-ray plate is kept along the left or right thigh perpendicular to the table; X-ray beam comes from across the table, centered over the greater trochanter. So, a dead lateral view is taken. This view is of importance in suspected HD and anorectal malformations. In the prone position with pelvis elevated, the gas rises in the rectum. If X-ray shows rectal gas, it almost rules out HD. In anorectal malformations, the distance between the rectal gas and the skin is measured. If it is less than 1 cm, then a primary perineal anoplasty operation can be done. If more than 1 cm, then colostomy should be done and definitive repair deferred for few weeks. The invertogram has become obsolete.

### Contrast Studies

Upper GI contrast studies help in diagnosing proximal bowel obstructions, such as malrotation and duodenal stenosis; lower GI contrast (enema) in lower GI obstructions such as HD and meconium disease. If there is too much gas on plain film, a contrast enema will be helpful and vice versa. Generally, the diagnostic study should be performed with nonionic water-soluble contrast.

### Upper Gastrointestinal Series

The most important and frequent indication is to confirm or exclude malrotation in a neonate presenting with bile-stained vomiting. Normal location of the duodenojejunal junction (DJ) is above and to the left of transpyloric plane. Any abnormality in the location of DJ means malrotation irrespective of other findings. Midgut volvulus may be evidenced by corkscrew appearance of proximal jejunal loops in addition to an abnormally located DJ. One more possible use of upper GI series is in partial upper small bowel obstruction such as duodenal or jejunal stenosis, band obstruction and internal herniation. In such cases, the presentation is usually not in the neonatal period but a few weeks after birth.

### Lower Gastrointestinal Study (Contrast Enema)

It is performed under antibiotic cover. Diagnosis is made with water soluble nonionic contrast. Dye is instilled per rectum till the dilated loops are filled in. If the dye reaches the dilated loops, it rules out atresia. In suspected meconium ileus, there will be microcolon (colonic diameter less than 1 cm). The differential diagnosis of microcolon includes MI and its variants, total colonic aganglionosis and distal ileal atresia.

Appearance of soap bubble appearance on plain film and microcolon in contrast enema calls for therapeutic enema with Gastrografin. Gastrografin contains surface active agents and will dissolve the thick tenacious meconium from the terminal ileum which will be passed per rectum relieving the obstruction. Enema may have to be repeated several times for the first few days to be clinically effective. Care should be taken to hydrate the patient well so that fluid shifts into the bowel lumen and does not cause intravascular dehydration and circulatory insufficiency.

### Ultrasound

It has limited role for evaluation of neonatal obstructions. In suspected malrotation, it is used to see the relationship of the superior mesenteric artery (SMA) and the superior mesenteric vein (SMV). Normally, the SMV is to the right of SMA (same as inferior vena cava and aorta). In malrotation, this is reversed. One can also see corkscrew appearance of jejunal loops in volvulus. Cystic and solid masses can be assessed with ultrasound. A child with distension at birth is a good indication for ultrasound. Rarely, neonatal appendicitis and intussusception can be picked up.

### Principles of Preoperative Management

Provide general neonatal care with monitoring of temperature and SpO<sub>2</sub>. Pass nasogastric (NG) tube and aspirate contents. Leave it on free drainage. Replace NG losses with normal saline every 6 hour. Establish IV access, draw samples for blood tests and start fluid resuscitation. Monitor serum Na and K, and urine output. Send blood sample for hematocrit, counts, urea, electrolytes. Start broad-spectrum antibiotics. A cephalosporin and metronidazole combination is sufficient in most cases. Once hemodynamically stable, obtain a plain abdominal film in AP view. Consult the surgical team and decide, if further contrast study is required. Surgical management will depend on the condition. **Table 1** gives a summary of the management of different conditions. Laparotomy should be planned only after adequate resuscitation and diagnostic work-up. However, there is one exception—malrotation with midgut volvulus, which can be a dire emergency. A description of this anomaly follows for better understanding of the pathophysiology and the nature of emergency.

### MALROTATION WITH MIDGUT VOLVULUS

This is a congenital abnormality that makes the midgut prone to twist in a clockwise manner around the superior mesenteric vessels due to a very narrow base of the mesentery (**Fig. 2**). It results from failure of rotation and fixation of the midgut during 8–12 week of intrauterine life. The DJ junction is abnormally located to the right of midline, the duodenum and cecum are juxtaposed close to each other, and a band (Ladd band) runs from the retroperitoneum across the cecum and duodenum.

Clinical features may be due to volvulus of the small bowel around SMA (most common and most dreaded) or chronic duodenal obstruction due to Ladd bands or due to an intrinsic duodenal stenosis. Volvulus of the midgut occurs most frequently within the first week of life with sudden onset of bile vomiting on 3–5th day. Rapid deterioration occurs because of gut ischemia and the child may present in shock. A quick resuscitation should be followed by an upper GI study, if the child is resuscitable. Many a time laparotomy is required urgently as part of resuscitation. The key to surgery is the root of the mesentery. The volved gut is untwisted, mesentery is widened and Ladd band is divided (**Fig. 3**).

### DUODENAL OBSTRUCTION

Congenital duodenal obstruction can occur because of atresia, stenosis, perforate or imperforate webs and extrinsic compression by bands or duplication cysts. Annular pancreas can cause a total or partial obstruction and may be indistinguishable from atresia. Duodenal atresia arises from failure of recanalization in utero.

Duodenal atresia, the most common cause of duodenal obstruction, occurs in 1 per 5,000 livebirths. 25% cases have associated Down syndrome. In 80% cases, the obstruction is distal to the ampulla of Vater resulting in bilious vomiting. In 20%, it is preampullary causing nonbilious vomiting. Antenatal ultrasound shows polyhydramnios and dilated stomach and duodenum. Duodenal atresia is the most frequent prenatal diagnosis amongst bowel obstructions. Since associated cardiac defects and Down syndrome are common, prenatal diagnosis becomes important to facilitate parental decision on medical termination of pregnancy. Therefore, detection of polyhydramnios with a dilated bowel loop on prenatal ultrasound is an indication of amniocentesis for chromosomal analysis to screen for Down syndrome.

Treatment is surgical. Duodenoduodenostomy is performed under general anesthetic. Postoperatively total parenteral nutrition (TPN) may be required for a few days till the duodenal motility is restored. Prognosis is good if Down syndrome is not associated.

**Table 1** Summary of the management of neonatal intestinal obstruction according to the underlying condition

Condition	Clinical features	Imaging	Treatment	Remarks
Duodenal atresia	Within few hours after birth, bilious vomiting, no abdominal distension	Double bubble sign on plain X-ray	Duodenoduodenostomy	<b>Etiology:</b> <ul style="list-style-type: none"> <li>Failure of canalization</li> <li>Twenty-five percent have Down syndrome.</li> </ul> <b>Differential diagnosis:</b> <ul style="list-style-type: none"> <li>Annular pancreas, duodenal stenosis, duodenal diaphragm</li> <li>Prognosis good if no chromosomal abnormality</li> </ul>
Jejunal atresia	Within 24 hours, bilious vomiting, mild distension	<ul style="list-style-type: none"> <li>Few dilated bowel loops in upper abdomen</li> </ul>	Resection of atresia and end to end anastomosis	<b>Etiology:</b> <ul style="list-style-type: none"> <li>Intrauterine vascular accident</li> <li>Prognosis good</li> </ul>
Ileal atresia	Within 24–48 hours, progressive significant distension, late vomiting, may pass meconium	<ul style="list-style-type: none"> <li>Many dilated loops with air fluid levels on plain film</li> <li>Microcolon on contrast enema</li> </ul>	Resection of atresia and end to end anastomosis	Resect about 5 cm on either side of atresia (poor myoelectric property) and to eliminate lumen disparity.
Meconium ileus	Almost immediately after birth, distension and bilious vomiting, no meconium passed or very tenacious meconium	<ul style="list-style-type: none"> <li>Soap bubble appearance on plain film</li> <li>Microcolon on contrast enema</li> </ul>	<ul style="list-style-type: none"> <li>Gastrografin enema may be therapeutic</li> <li>Laparotomy may be required</li> </ul>	<ul style="list-style-type: none"> <li>Repeat Gastrografin enema may be required</li> <li>Investigate for cystic fibrosis</li> <li>Exclude HD by rectal biopsy</li> </ul>
Hirschsprung disease	No meconium in 24 hours, gradual soft distension, no vomiting despite massive distension (distension because of colonic dilatation)	<ul style="list-style-type: none"> <li>No rectal gas on cross table prone X-ray</li> <li>Transition zone on contrast enema</li> </ul>	<ul style="list-style-type: none"> <li>Rectal washouts for 6–8 weeks</li> <li>Primary pull through at 6–8 weeks</li> <li>May require urgent colostomy</li> </ul>	<ul style="list-style-type: none"> <li>Rectal biopsy is diagnostic</li> <li>Atypical presentation likely in total colonic aganglionosis</li> <li>May present as acute small bowel obstruction requiring colostomy</li> </ul>
Malrotation with midgut volvulus	Within 3–5 days, sudden onset bilious vomiting, rapid deterioration to shock	Plain film may be normal, abnormal location of DJ on upper GI contrast study	<ul style="list-style-type: none"> <li>Urgent Ladd's procedure</li> <li>No time for imaging</li> </ul>	<ul style="list-style-type: none"> <li>In 90% cases, volvulus occurs within the first month of life</li> <li>May also present with recurrent chronic duodenal obstruction.</li> </ul>

Abbreviations: HD, Hirschsprung disease; DJ, duodenojejunal junction; GI, gastrointestinal tract.

**Figure 2** Malrotation with midgut volvulus. Note the twisted bowel on narrow mesentery (double arrow)

**Figure 3** Malrotation. The bowel has been untwisted; mesentery has been widened (dotted line)

Abbreviations: ICJ, ileocaecal junction; DJ, duodenojejunal flexure.

### JEJUNOILEAL ATRESIA (FIGS 4 to 7)

Intestinal atresia refers to a congenital absence of bowel lumen resulting in total obstruction. Unlike duodenal atresia, Jejunoileal atresia is believed to be caused by an intrauterine mesenteric

vascular accident. The most common type is type III wherein there is separation of the two ends with a V-shaped defect in the mesentery. Unlike duodenal atresia the incidence of associated malformations is very low.

Clinical symptoms in intestinal atresia depend upon the location of atresia. In proximal obstructions, such as duodenal and jejunal atresia, the abdomen is not distended or minimally distended; onset of bilious vomiting is early. Abdominal distension is much less and is limited to upper abdomen in proximal atresia. If there is proximal obstruction (duodenal or jejunal), the decision for surgery is simple and could be based on plain X-ray alone. The approach may be quite different for distal ileal or colonic obstruction because surgery may not always be required urgently (as in meconium ileus, HD). A contrast enema is required to differentiate ileal atresia from meconium ileus, HD and colonic atresia. In distal ileal atresia, the dye will not reach the dilated segment and there will be microcolon. In HD, a transition zone will be seen. In meconium ileus, the Gastrografin enema may be therapeutic. Treatment of intestinal atresia is by resection of the atresia and end to end anastomosis. Prognosis is good.

### HIRSCHSPRUNG DISEASE (HD) IN THE NEWBORN

Hirschsprung disease can present in the neonatal period as failure to pass meconium within 24 hours of birth, or full blown small bowel obstruction.

**Figure 4** Jejunal atresia. Plain X-ray in supine and lateral decubitus views. Only proximal loops are dilated with no distal gas

**Figure 5** Operative picture of the same patient as in Figure 4. Note the type I atresia in the proximal jejunum. The proximal bowel is hugely dilated as compared to the distal bowel

**Figure 6** Mid-ileal atresia. Note many dilated bowel loops with air fluid levels

**Figure 7** Operative picture of the same patient as in Figure 6. Note the type III atresia and the difference in the lumen of proximal and distal bowel. This was an *Apple Peel* atresia

### Failure to Pass Meconium within 24 hours

This is the most common presentation. Gradually, abdominal distension occurs. The child continues to accept feeds and there is no vomiting. Plain X-ray (**Fig. 8**) shows many gas filled loops all over the abdomen. Prone cross table lateral view (**Fig. 9**) shows no gas in the rectum. Diagnosis is made by contrast enema which shows typical transition zone (**Fig. 10**). Rectal biopsy provides the most definitive diagnosis. In the biopsy specimen, the acetylcholinesterase activity is raised, ganglion cells are absent and nerve bundles are hypertrophied.

### Management

The baby is put on rectal washouts with normal saline twice or thrice daily to help bowel decompression. Oral feeds are given. Child is sent home on daily rectal washouts. At 6–8 weeks, when the child has shown satisfactory growth, a definitive pull through operation is performed. The current trend is to perform open or laparoscopic primary pull through. If response to washouts is not good, a stoma may need to be created. At operation the transition zone is identified as shown in **Figure 11**.

**Figure 8** Plain X-ray in Hirschsprung disease (HD). Note peripherally dilated loops suggestive of large bowel loops. Also the pelvic gas is deficient

**Figure 9** Prone cross table view in Hirschsprung disease (HD). Note the transition zone

**Figure 10** Contrast enema in the same patient as in Figures 8 and 9. Rectosigmoid transition is seen. Note that the same information is obtained on prone cross table lateral film

**Figure 11** Operative picture showing the transition zone (double arrow) in HD  
Abbreviations: R, rectum; S, sigmoid colon; HD, Hirschsprung disease.

### Full Blown Small Bowel Obstruction

Full blown small bowel obstruction with bilious vomiting, distension and failed passage of meconium is often difficult to differentiate from ileal atresia. This presentation is usually seen in total colonic aganglionosis. Contrast enema is helpful in diagnosis. It shows microcolon with a rounded splenic flexure. Proximally, there are several dilated loops of small bowel. An urgent laparotomy is required with creation of a stoma.

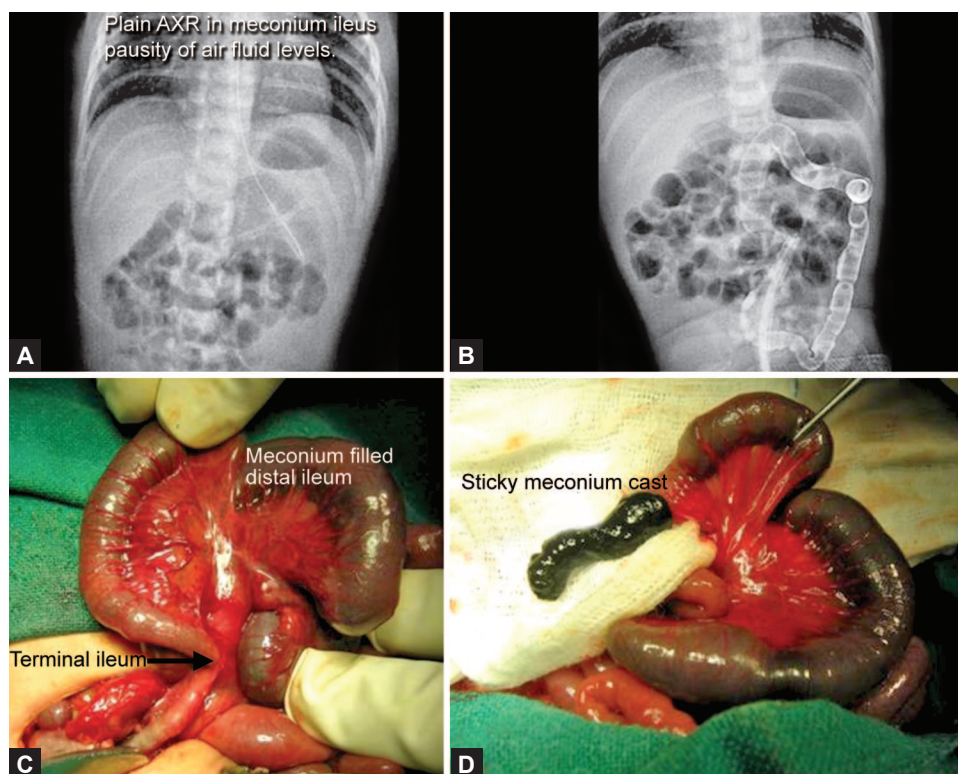

### MECONIUM ILEUS (MI)

It is characterized by retention of thick and tenacious meconium in the distal small bowel causing obstruction. Pancreatic deficiency and cystic fibrosis (CF) are known to be associated in about 80%. Seen in 15% cases of CF, MI is the earliest manifestation of CF. The meconium is rich in proteins making it thick and viscid. There is further contribution by decreased gut motility and defective secretory properties leading to increased mucin content in the meconium. Antenatally, this can be picked up on ultrasound as hyperechoic bowel contents. Suspicion of MI with a family history

of CF should lead to amniocentesis for evaluation of delta F508 mutation on the CF gene and DNA polymorphism. If positive, the pregnancy should be terminated.

Postnatally, the presentation may be that of *simple MI* or *complicated MI*. Simple MI (**Figs 12A to D**) presents with abdominal distension at birth, bilious vomiting and failure to pass meconium. Distension gradually increases. The dilated bowel loops may be visible and may indent on pressure. Digital rectal examination is difficult as the small rectal caliber does not allow insertion of the finger. Complicated MI may have volvulus, atresia, perforation meconium peritonitis or giant cystic meconium peritonitis. At birth, severe abdominal distension is usually present with erythema of the wall. A palpable mass may be there suggesting a cyst formation. Perinatal perforation may also lead to tracking of meconium into the scrotum through a patent processus vaginalis. Plain X-ray in simple form shows a soap bubble appearance in the right lower abdomen due to mixing of air and meconium. Proximal loops are dilated but air fluid levels are not many. Complicated form may show calcification indicating antenatal bowel perforation (**Figs 13A and B**). A mass

**Figures 12A to D** Simple meconium ileus. (A) Plain X-ray showing few dilated small bowel loops but no air fluid levels; (B) Contrast enema showing microcolon; (C) Operative: distal ileum collapsed. Proximal ileum filled with thick meconium; (D) Dilated ileum opened to reveal thick tenacious viscid meconium

**Figures 13A and B** Complicated meconium disease. (A) Plain X-ray showing dilated loops and calcification (single arrow). The large blob of air in left iliac fossa is due to a perforation resulting in air filled meconium cyst (double arrow); (B) Operative: the cyst has been opened. Calcified area is also seen (double arrow)

effect may be seen due to cyst formation. Contrast enema shows microcolon. The dye refluxes into the ileum showing meconium pellets as filling defects. In simple MI, Gastrografin enema may be therapeutic as described earlier.

Nonoperative treatment with Gastrografin can be attempted when other surgical causes have been ruled out; the child is well hydrated and antibiotics have been given. Possible complications are rectal and small bowel perforation, hypovolemic shock and necrotizing enterocolitis (NEC). Success rate with this approach is about 50–60 % only. In the rest and in complicated variety of MI, a laparotomy is indicated.

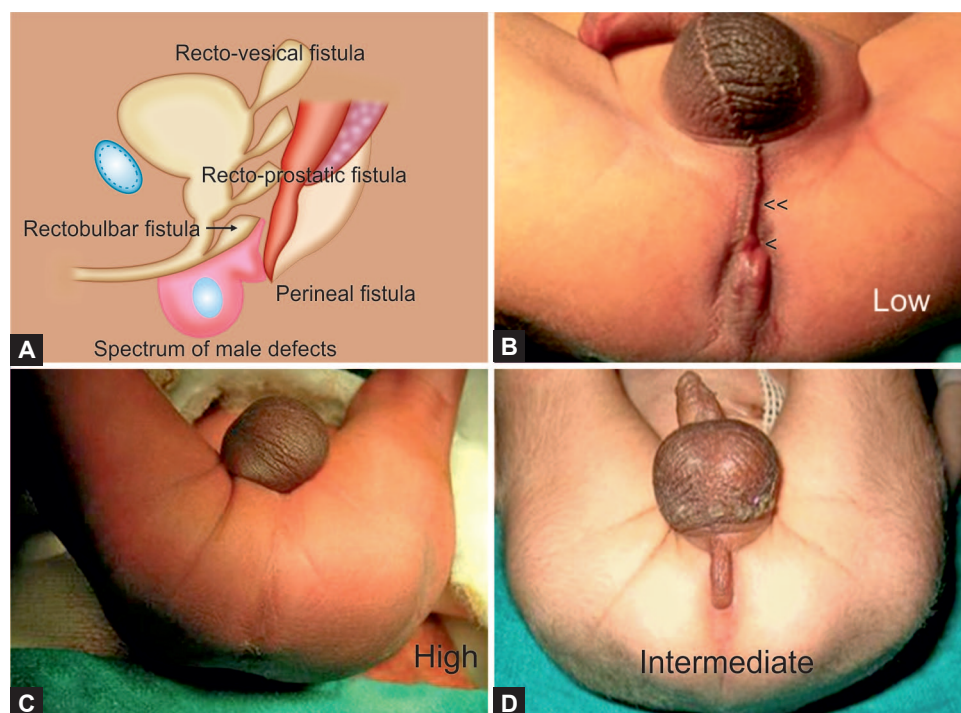

## ANORECTAL MALFORMATIONS

Anorectal malformation (imperforate anus) is a congenital defect in which the child is born without an anal orifice. It occurs in a spectrum and is described separately for boys and girls.

### Anorectal Malformation in Boys (Figs 14A to D)

The rectum terminates either above (*high malformation*) or below (*low malformation*) the levator ani. In high malformations the rectum terminates in the urinary tract through a rectourinary fistula, the level of which may vary from recto-bladder fistula to rectobulbar urethral fistula. Rectobulbar fistula is the commonest malformation. In low malformations, the rectum terminates within about a cm from the skin; there is no rectourinary communication and often the meconium shows up in the perineum through a small opening (perineal fistula) either at the site of normal anus or along the median raphe in the scrotum (anocutaneous fistula). The diagnosis should be made in the delivery room by inspecting the perineum—no anal opening is found. The next step is observing for meconuria—passage of meconium in urine. Meconuria with absence of anal opening in the perineum invariably indicates a high malformation which requires a colostomy in the newborn period. Low malformations do not become evident until 24 hours (which is the time taken for meconium to descend down the gut) when the meconium may show in the perineal fistula. These defects can be managed by a perineal anoplasty without a colostomy in the newborn period.

Associated malformations are seen in 50–60% cases, out of which nearly two-thirds are genitourinary, 25% vertebral, 20% cardiac and 10% GI. 15% have VACTERL or CHARGE association. High malformations have higher chances of associated malformations.

**Figures 14A to D** Spectrum of anorectal malformations in males. (A) Schematic diagram showing different levels at which the rectum can terminate either into the urinary tract or on the perineal surface; (B) Low malformation. Perineal fistula or anal stenosis (single arrow). Note the thin subepithelial tract along the midline scrotal raphe (double arrow); (C) Flat perineum with no anal dimple indicates high malformation; (D) Good perineum with pigmented anal dimple indicates intermediate anomaly probably rectobulbar urethral fistula

### Perineal Examination and Imaging

**Examine perineum** There is no anal opening. Look for gluteal fold, natal cleft and palpate spine or sacrum. Is it a flat bottom? Is there a dimple at the anal site with pigmentation? Is anocutaneous reflex present? Is there a fold of skin under which you can pass a probe (bucket-handle deformity)? Is there any mass? Can you see a thin white epithelial thickening in the median raphe—suggests anocutaneous fistula? Is there any speck of meconium in the perineum—perineal fistula? Is there any abnormality of the external genitalia—bifid scrotum, hypospadias and undescended testes? Look for evidence of meconuria—gas or meconium discharge per urethra.

**Prone cross table lateral shoot abdominal film (Fig. 15)** It is required if clinical information at 24 hours is insufficient to decide whether a colostomy is needed. The technique has been described under the general imaging section. The distance of rectal gas from the skin marker is measured. If less than 1 cm, a perineal anoplasty is performed; there is no need for a colostomy. If more than 1 cm, a colostomy is opened.

### Indicators of High Anomaly where a Colostomy is Indicated

No meconium in the perineum at 24 hours, flat bottom, absent anal dimple or pigmentation, absent anocutaneous reflex, sacral abnormality, meconium in urine (or gas in bladder on X-ray), suggestion of a pouch colon on plain abdominal film and associated bifid scrotum, proximal hypospadias or bilateral undescended testes.

### Indicators of Low Anomaly (Suitable for Primary Anoplasty)

Good perineum, pigmented dimple, anocutaneous reflex, visible fistula in the perineum, bucket-handle deformity—a bridge of skin

over the anal site under which an instrument can be passed and meconium can be seen under the skin.

When a colostomy is performed at birth, the definitive pull through operation is performed at few weeks. In the waiting period, the following investigations are carried out: echocardiography, renal ultrasound, sacral X-ray to determine sacral ratio, X-ray spine, and distal cologram. Primary pull through without a colostomy is also performed by some surgeons at birth. However, it requires a careful selection of patients (no cardiac malformation, good weight, no major distension and no meconuria). Miniature cystoscope is used to locate the site of rectourinary fistula.

### Anorectal Malformation in Girls

Most anomalies in girls are low and the hindgut opens within the vestibule through a small opening referred to as *anovestibular fistula* (Fig. 16). This is the commonest anorectal malformation in females. Bowel is decompressed but not adequately. The opening is very small often hidden in the posterior fourchette behind the vagina and it requires diligent examination in good light to identify the anovestibular fistula. At times the opening is easily seen, is wider, and has anal folds visible—this is called *vestibular anus* (Fig. 17). The bowel decompression is better. The number of openings in the vulva gives a good guide for diagnosis of anorectal malformations in females (Figs 18A to D):

- **Three openings:** Anovestibular fistula (commonest), rectovestibular fistula, perineal fistula, anterior ectopic anus
- **Two openings:** Rectovaginal fistula (rarely vestibular fistula with vaginal atresia)
- **One opening (Cloaca):** The vulva is small. The child passes urine and stools through the common opening. The vagina may be distended (hydrocolpos) and present as a lower abdominal mass. Urinary system may be obstructed.

**Figure 15** Prone cross table view in a case of rectobulbar urethral fistula. This is the commonest anomaly in males. The distance between the skin marker (\*) and the rectal gas is shown by dotted line. The rectal gas has descended beyond the coccyx. The perineal appearance is as shown in Figure 14D

**Figure 16** Anovestibular fistula: the commonest anorectal malformations (ARM) in females. Note the small opening behind the vagina in which an instrument has been passed to visualize it. There is a catheter in the urethra

**Figure 17** Vestibular anus. Note the anal folds and a larger easily identifiable opening. There are three openings in the vulva  
Abbreviations: U, urethra; V, vagina.

### Management

- **Anovestibular fistula:** Aim of immediate neonatal management is to ensure gut decompression. This may require gentle dilatation of the anovestibular fistula with or without saline rectal washouts. Elective repair is undertaken at few weeks of age. Usually no colostomy is required.
- **Cloaca:** Urgent investigations are done to assess urinary tract and vagina. Usually a transverse colostomy is performed at birth. If there is hydrocolpos, a vaginostomy is also carried out.
- **Rectovaginal fistula:** It is a rare malformation. It requires a colostomy at birth. Mayer-Rokitansky syndrome should be excluded.

### UMBILICAL AND ABDOMINAL WALL MALFORMATIONS

During the 3rd week of gestation, three embryological folds (cephalic, lateral and caudal) determine the formation of anterior abdominal wall. They have splanchnic and somatic components.

**Figures 18A to D** Spectrum of anorectal malformations (ARM) in females. Perineal examination and number of openings in the vulva is the key to diagnosis. (A) Normal anatomy; (B) Three openings, anovestibular fistula (commonest); (C) Two openings, rectovaginal fistula; (D) Single opening (cloaca)

Splanchnic components are the embryonic foregut, midgut and hindgut respectively. Somatic components form the abdominal wall. Abnormal folding may result in a variety of defects:

- **Cephalic fold defect:** Epigastric omphalocele, diaphragmatic defects, chest wall defects, Cantrell's pentalogy.
- **Lateral fold defect:** Omphalocele or exomphalos, hernia of umbilical cord. Normal folding results in the formation of umbilical ring which closes after the return of midgut from the extra embryonic coelom. Abnormal folding and delayed return of the midgut cause failed closure of umbilical ring allowing herniation of gut or liver through the wide ring. With folding process, the yolk sac is also displaced by the amniotic cavity and the connection between the yolk sac and the

midgut, omphalomesenteric duct, obliterates. This leads to the formation of cord like body stalk which contracts to form the umbilical cicatrix.

- *Caudal fold defect:* Hypogastric omphalocele, exstrophy bladder, cloacal exstrophy.

### Exomphalos and Hernia of Umbilical Cord (Fig.19)

Exomphalos or omphalocele is a herniation of intra-abdominal viscera through a wide umbilical ring into the base of the umbilical cord. There is a three layered covering membrane comprising of parietal peritoneum, Wharton jelly and amnion. When the width of the ring is more than 4 cm, it is termed as exomphalos. If it is less than 4 cm, it is called hernia of the umbilical cord. Large

Figure 19 Exomphalos

defects cause liver herniation also. Hernia of the umbilical cord never contains the liver. Associated malformations are frequent and determine survival and outcome. On antenatal ultrasound, the condition can be differentiated from physiological state of gut evisceration by identifying the liver as content. Liver is never a part of physiological herniation. Decision for termination of pregnancy should be taken only if the diagnosis has been confirmed and amniocentesis shows abnormal karyotype or there is associated cardiac defect.

If pregnancy is continued, the mother should be referred to a higher center for an elective Cesarean section at term. Postnatal management should aim at prevention of traumatic rupture of the sac, prevention of sepsis and assessment for associated cardiac malformations. The baby should be nursed supine with the sac supported on both sides. Dilute povidone iodine or Mercurochrome (0.5% in alcohol) may be applied on the surface to facilitate epithelialization. The resulting skin covered ventral hernia can be closed at 6 months or later. Urgent surgery may be required if the sac ruptures or there is intestinal obstruction. Primary closure should be done if possible. Often a silo pouch is needed.

### Gastroschisis (Figs 20A to C)

During development of the abdominal wall, the right umbilical vein disappears, leaving a relatively weak area to the right of umbilical ring. Due to a possible vascular insult if this weak area gives way, it leads to evisceration of the bowel, referred to as gastroschisis. Since there is no peritoneal sac, the gut is exposed to urea rich amniotic fluid leading to edema, thickening and at times stenosis. The differences between gastroschisis and exomphalos are shown in the Table 2.

The delivery should occur by an elective cesarean section at term in a tertiary care center. The eviscerated gut should be immediately

**Figures 20A to C** Gastroschisis. (A) The defect is to the right of umbilicus. The gut has no covering membrane; (B) The gut has been covered by skin alone as the fascial covering was not possible due to less space in the abdomen; (C) Resultant ventral hernia after few months. This will be closed in stages

**Table 2** Differences between exomphalos and gastroschisis

Criterion	Exomphalos	Gastroschisis
Embryology	Insult in formation of lateral embryonic fold. Umbilical ring remains wide allowing herniation	Weakness to the right of umbilicus due to regression of right umbilical vein. Umbilical cord normal
Timing	Early in 3rd week	Late second trimester or perinatal. Late event associated with less bowel problems—less exposure to amniotic fluid
Covering	Peritoneum, Wharton jelly and amnion	None
Contents	Gut and liver. Gut is healthy and normal	Gut. It is edematous, may have stenosis or atresia
Associations	Forty percent Cardiac, trisomy 18, Beckwith–Wiedemann syndrome. Less intestinal malformations	Uncommon. Intestinal stenosis and atresia more frequent due to exposure to amniotic fluid
Other associations	Multifactorial etiology	Young mothers, intrauterine growth restriction (IUGR), drug abuse
Treatment	Conservative or surgical	Surgical. Primary closure, skin closure, silo
Prognosis	Bad. Related to associated malformations	Good if gut healthy. Problem related to bowel dysfunction. Needs parenteral nutrition

covered by a cling film to prevent fluid and heat loss. The baby is nursed supine to prevent drag on the mesentery. A quick survey should be made for other anomalies. Intravenous access should be obtained and a fluid bolus given. Surgery should be performed promptly within few hours of birth. Primary fascial closure is the best treatment but may not be possible due to less space in the abdominal cavity and edematous bowel. In that case only skin closure may be obtained and the resultant ventral hernia repaired after few months. In very severe cases, a silo pouch needs to be made. The silo is tightened every day to aim at formal wall closure by 6th or 7th day.

### Meckel's Diverticulum and Related Malformations

Vitelointestinal duct, which normally disappears after the formation of umbilical cicatrix, may persist to cause a spectrum of abnormalities:

- *Meckel's diverticulum*: Persistence of duct at intestinal end
- *Meckel's band*: Fibrous remnant of the duct and its blood supply
- *Umbilical sinus*: Patent distal end of the duct
- *Patent vitelointestinal duct (PVID)*: A completely patent duct causing communication of intestinal lumen to the surface
- *Umbilical polyp*: Proliferation of tissue at the distal end with a persistent Meckel's band running from the umbilicus to midgut and umbilical cyst.

PVID is very evident at birth because it leads to bilious discharge from the umbilicus. Urinary discharge may be due to persistent lumen in the urachus—a remnant of allantois. Meckel's diverticulum may present as an emergency due to inflammation and perforation, bleeding from ectopic gastric mucosa or intestinal obstruction by volvulus around the Meckel's band.

### Umbilical Granuloma

It is a proliferation of granulation tissue during the process of falling off of the umbilical cord in immediate neonatal period. Generally presents as pinkish growth with serous- or blood-stained discharge. It responds to chemical cautery by silver nitrate. Large granulation may require electrical cauterization. They should be distinguished from umbilical polyp which results from persistence of a portion of vitelointestinal duct, which is present at birth, contains mucosal lining, discharges mucus and does not respond to cauterization.

### Umbilical Hernia

It is different from hernia of the umbilical cord. The umbilical cicatrix is largely formed well but is weak leading to herniation of

bowel in the first few days to weeks after birth, the overlying skin is normal and one can feel the small defect in the umbilical cicatrix through the skin. The hernia becomes more prominent when the child cries. Often the parents blame the hernia for crying (although it is the reverse). Most of these hernias resolve spontaneously within the first 2 years of life. Strapping over coins, although frequently practiced should not be done, as it may lead to skin maceration and allergies. Surgery should be offered to persistent hernias beyond 2–3 years. Complications in the form of obstruction, strangulation and perforation are rare.

### IN A NUTSHELL

1. A baby, who was born normal and healthy and took feeds well but develops bilious vomiting on the 3rd or 4th day and becomes limp and pale suddenly, is most likely to have acute midgut volvulus because of malrotation. Quick fluid resuscitation and urgent laparotomy, as part of continuing resuscitation, may be lifesaving.
2. Intestinal atresia and Hirschsprung disease (HD) are the most common causes of neonatal intestinal obstruction.
3. Bile-stained vomiting and abdominal distension are cardinal signs of neonatal intestinal obstruction.
4. Plain X-ray abdomen is the single most important diagnostic investigation for neonatal intestinal obstruction.
5. Failure to pass meconium within 24 hours of birth should alert for HD. Eighty percent of all cases of HD are diagnosed at birth. They should be managed by rectal washouts initially followed by early definitive pull through without colostomy.
6. Contrast enema using Gastrografin may be therapeutic for simple meconium ileus.
7. Most anorectal malformations in males are high type with rectourinary communication. They usually require a colostomy at birth. Most anorectal malformations in females are low type which can be managed without a colostomy at few weeks of age.
8. Invertogram is obsolete. Prone cross table lateral film gives useful information about the level of the malformation.
9. Omphalocele is associated with systemic malformations of other systems, such as cardiac defects, while gastroschisis is associated more with intestinal obstruction due to local factors.
10. Omphalocele with intact sac may be managed conservatively, but gastroschisis should be repaired within few hours after birth.

## Chapter 18.4

# Genitourinary Malformations

Satish Kumar Aggarwal

Genitourinary malformations (GUM) account for 50% of all malformations detected on antenatal ultrasound scan. Nearly two-thirds of them are hydronephrosis. Antenatal ultrasound has made a huge impact on diagnosis and management of these malformations by providing insight into their pathogenesis and natural history. Fetal magnetic resonance imaging (MRI) and other modalities have helped in confirming diagnosis and decision making regarding medical termination of pregnancy in select cases of multiple or life-threatening malformations. In most cases, the pregnancy can be continued till term and delivery can take place in a tertiary care center where better neonatal facilities including surgical care are available. Parental counseling is also an important aspect of the care. A small subset of patients may be candidates for in utero interventions, but their results have been disappointing. Stem cell technology and advances in regenerative medicine is the key to future postnatal management of some of these malformations, e.g., laboratory manufactured bladder from stem cells may be the future treatment of bladder exstrophy.

## EMBRYOLOGICAL BASIS

A working knowledge of embryology is essential to understand the genesis, morphology and functional implications of GUM. Organogenesis occurs during 3–10 weeks of gestation. Maturation, growth and development continue until term. In the embryonic disc, at an early stage, the mesoderm is arranged in three areas: paraxial, intermediate and lateral plate mesoderm. The genitourinary system originates from the intermediate mesoderm. The cervical portion of the mesoderm (pronephros) disappears, the middle portion (mesonephros) develops into the gonads and the distal portion (metanephros) becomes the kidney. Migration of primordial germ cells from the yolk sac to the mesoderm initiates formation of gonads and the genital ducts. Mesonephric (wolffian) duct communicates with the primitive cloaca which separates into the urinary tract anteriorly and the hind gut posteriorly by ingrowth of urorectal septum. The mesonephric duct develops into the epididymis, vas and seminal vesicles and its communication with the urinary system stays intact as it drains into the urethra as ejaculatory duct. The ureteric bud originates from the mesonephric duct at 4–5 weeks and as it grows outward, it hits the metanephros to initiate nephrogenesis at 6 weeks. The glomeruli of the kidney originate from the metanephros and the collecting system including the pelvicalyceal system and the ureter originate from the ureteric bud. The kidney is formed lower than the gonad but later the kidneys ascend upward and the gonads descend downward. While the kidney derives its blood supply sequentially at different levels, the gonads carry their blood supply with them from the site of origin. Fetal urine production, which starts at 10–12 weeks, contributes for 90% of the amniotic fluid volume. By 14–16 weeks, the genitourinary system is developed nearly completely and antenatal ultrasound can pick up congenital malformations.

In females the paramesonephric (müllerian) ducts develop lateral to the mesonephric (Wolffian duct). Absence of testosterone leads to regression of mesonephric ducts after the ureteric bud has originated for renal and ureteric development at about 6 weeks. The proximal part of paired paramesonephric ducts gives origin to the fallopian tubes while the distal portion, which crosses over to midline and fuses together (uterovaginal canal), gives rise to

uterus and proximal vagina. The distal vagina develops from the urogenital sinus. Therefore, a blind stump of vagina is seen to persist in conditions such as androgen insensitivity syndrome and vaginal (Müllerian) atresia.

Differentiation of external genitalia occurs during 12–16 weeks. Clitoris and phallus develop from genital tubercles, urethra and labia minora from genital folds and the scrotum and labia majora from genital swellings.

## Ureteric Bud Theory

The site of origin of the ureteric bud from the mesonephric duct determines the fate of future kidney and ureters. Normal renal development requires origin of ureteric bud at the normal site on the mesonephric duct. Ureteric bud abnormalities are responsible for a number of anomalies: lateral ureteral ectopia (caudal origin of ureteric bud), duplex system with ureterocele (two ureteric buds), renal dysplasia (off the mark origin of ureteric bud), etc. In complete duplication anomalies of ureteric bud, the upper moiety ureter always opens on the bladder distal and medial to the lower moiety ureter (Weigert-Meyer Law). The upper moiety is also more likely to be dysplastic as the ureteric bud for this moiety does not hit the normal metanephric blastema.

Since embryogenesis progresses simultaneously in several organ systems, an insult to the process is likely to produce multiple malformations—a fact responsible for associations like VACTERL (vertebral, anorectal, cardiac, tracheoesophageal, renal and limb). Renal agenesis on one side is often associated with absent vas or Müllerian agenesis on the ipsilateral side. Similarly 30% cases of high anorectal malformations have associated GUM. Complex embryological processes are involved in rare duplication anomalies with congenital masses. Duplication anomalies may be a spectrum of caudal duplication syndrome with bizarre clinical appearances coupled with varying degrees of internal organ duplications (Fig. 1).

## RENAL MALFORMATIONS

### Renal Agenesis

Unilateral renal agenesis is usually a silent condition, incidentally detected on ultrasound. It may reflect an intrinsic defect of the embryonic mesenchyme, hence association with absent vas and Müllerian agenesis on the ipsilateral side. While operating for hernia in a child if vas is found to be absent, this finding should be

**Figure 1** Caudal duplication. Note two phallus and scrotal sacs. The child also has a presacral mass and anorectal malformation. Internally the bladder and rectum were duplicated

recorded and ultrasound carried out to check for renal agenesis. Bilateral renal agenesis is incompatible with life.

### Renal Dysplasia

Abnormal ureteric bud and/or severe embryonic urinary tract obstruction may lead to renal dysplasia characterized by small lobulated kidney with distorted primitive tubules and presence of cartilage and fibromuscular tissue. In cases of posterior urethral valves (PUV), varying degree of dysplasia occurs depending upon the severity and the timing of onset of fetal urinary obstruction. Most of this is genetically determined and is unlikely to benefit much from relief of urinary obstruction. Similarly, severe reflux is also associated with genetically determined renal dysplasia.

### Cystic Renal Malformations

The spectrum of cystic renal malformations in order of frequency is: multicystic dysplastic kidney (MCDK), autosomal recessive polycystic disease (ARPD), cystic renal neoplasms, and simple renal cysts. These disorders will be discussed separately in Section 41 on diseases of the kidneys.

### Horseshoe Kidney and Duplex Kidneys

A horseshoe kidney is characterized by fused lower poles of the two kidneys. Usually, it is an incidental diagnosis but occasionally obstruction at pelviureteric junction (PUJ) can occur in one or the other kidney. Diagnosis is confirmed on ultrasound. Magnetic resonance (MR) urogram gives good information about the anatomy as well as function (**Fig. 2**).

*Duplication anomalies* arise due to duplication of ureteric bud which may be complete or partial. Two ureteric buds originating separately on both sides culminate into bilateral duplex system. The upper moieties are usually dysplastic but normal function in all four moieties is also possible. Rarely, one of the moieties can have pelviureteric junction obstruction (PUJO) (**Fig. 3**). The ureters share a common vascular sheath but open at different sites in the bladder as per Weigert-Meyer law. Incomplete duplications causing Y-shaped ureters or split pelvis are largely inconsequential.

*Ureterocele* is a dilatation of the lower end of ureter. Usually, it is associated with duplex system with the upper moiety ureter terminating into an ureterocele. When large it may produce bladder neck obstruction in addition to ureteric obstruction. On imaging, such as intravenous urogram (IVU) and micturating cystourethrogram (MCUG), it appears as a filling defect in the bladder (**Fig. 4**). Often it requires emergency endoscopic deroofing soon after birth in order to relieve obstruction.

### Abdominal Mass at Birth

Kidney is the most common organ giving rise to an abdominal mass at birth. The most common is a giant hydronephrotic kidney caused by PUJ obstruction. Other cystic masses may be retroperitoneal lymphangioma, large ovarian cyst, omental or mesenteric cysts, distended vagina (hydrocolpos) and distended bladder. Solid masses could be congenital Wilms tumor (**Fig. 5**), neuroblastoma and retroperitoneal teratoma. Ultrasound and computed tomography (CT) should give a diagnosis. Giant hydronephrosis is usually associated with poor renal cortex and poor function. It should be managed by initial percutaneous nephrostomy. Renal function should be assessed after few weeks of drainage. If significant function recovers, pyeloplasty should be done. If not, a nephrectomy is indicated. Decision for nephrectomy should be taken carefully and when dimercaptosuccinic acid (DMSA) scan shows very poor (<10%) function. Some surgeons prefer a primary pyeloplasty. The opposite kidney should be assessed for concomitant pathology. Neonatal renal solid masses should undergo nephrectomy.

## EPISPADIAS-EXSTROPHY COMPLEX AND CLOACAL EXSTROPHY

A defect in the cloacal membrane during early embryogenesis may lead to exposure of the inner lining of the common cloaca on the surface there being no body wall in front. Depending on the timing of the embryonic insult, it can result in a spectrum of anomalies:

### Epispadias (Fig. 6)

The bladder is closed, but the urethra is exposed. The phallus has a dorsal chordee. The child may be continent or incontinent depending on the level to which the urethral plate is open. Treatment is surgical. It is carried out at the age of 1 year. In incontinent epispadias, bladder neck reconstruction is also required.

### Epispadias-Exstrophy Complex (Fig. 7)

In this classical form, the child is born with an exposed inner lining of the bladder and the urethra in its entire length. The ureteric orifices are exposed on the surface. The surrounding paraexstrophy skin is thin and shiny. The anus is anteriorly placed. In the male, the penis is short and dorsally curved with separation of corporal bodies. In the female, the clitoris is bifid. Vaginal stenosis and duplication may occur. The pubic bones are set wide apart (pubic diastasis). The anomaly looks gross but the child is otherwise normal, accepts feeds and there is no urinary obstruction. The upper tracts are usually normal. Prenatal diagnosis is suggested by absence of a normal bladder, anterior abdominal wall mass and low set umbilicus.

### Management in the Newborn

- Ligate umbilical cord with a long thread rather than clamp (clamp may traumatize the delicate bladder)
- Cover the exposed bladder by thin clear plastic sheet such as cling film. Gauge cotton may adhere and damage the epithelium. Avoid petroleum jelly or saline soaked gauge on the bladder. Put diapers over the cling film.
- Obtain a renal ultrasound to exclude upper tract anomalies such as duplex system.
- Surgical closure should be performed within 24–72 hours once the parents have been counseled and consented.

The initial surgery is closure of the bladder. Further surgery consists of bladder neck repair and epispadias correction. Many surgeons prefer a single stage total correction. The results regarding cosmesis and continence are variable. Many patients ultimately require bladder augmentation. Stem cell technology and tissue engineering have enabled bladders to be grown in the laboratory for transplantation. It is going to be the future of these malformations.

### Cloacal Exstrophy (Fig. 8)

It is a rare but complex anomaly comprising of a large exomphalos; two exposed hemibladders, one on each side of prolapsing terminal ileum in the center (often termed as elephant trunk appearance); two appendicular orifices and two ureteric orifices, one on each hemibladder. There is no anal opening in the perineum. Unlike classic bladder exstrophy, associated malformations are frequent. Neonatal work-up includes assessment for associated malformations and detailed discussion with parents about the outcomes. Surgical reconstruction is complex.

## HYPOSPADIAS

Because of the environmental androgen disruptors, increased use of chemical fertilizers and increased genetic pool, the incidence of hypospadias is steadily rising, current incidence being about 1 in

**Figure 2** MR urogram showing horseshoe kidney. Note VUR on the left. The child presented with UTI  
*Abbreviations:* MR, magnetic resonance; VUR, vesicoureteric reflux; UTI, urinary tract infection.

**Figure 3** Intravenous urogram (IVU) showing bilateral duplex system with all four moieties functioning. Right lower moiety has a dilated pelvis (asterisk) because of pelviureteric junction (PUJ) obstruction. The child underwent right lower moiety pyeloplasty

**Figure 4** Ureterocele seen as a filling defect (double arrow) in the bladder on MCUG. There is gross reflux in the lower moiety ureter

**Figure 5** Neonate with a flank mass. This was a Wilms tumor

**Figure 6** Epispadias. The phallus has been stretched to show the open urethral plate dorsally

**Figure 7** Classical Epispadias-Exstrophy complex. Exposed bladder plate is bulging. Phallus is short and turned dorsally

**Figure 8** Cloacal exstrophy. The central mucosa is from ileum. The two hemibladders are on the sides

150–200. It may have a genetic basis as suggested by transmission from father to son and among siblings. Babies born by in vitro fertilization techniques are at increased risk.

Hypospadias is defined as ventral hypoplasia of the penis. There is ventral deficiency of skin, dartos, spongy tissue and ventral urethral wall. The foreskin is dorsally crowded like a hood (hooded prepuce) and the glans is typically rotated outward, downward and laterally. The urethral opening is located on the ventral surface proximal to the site of normal opening. The meatus is often narrow giving rise to thin and forceful stream that falls between the legs of the patient. Often there is ventral curvature of the penis referred to as chordee. Hypospadias is classified depending upon the site of urethral meatus:

- **Anterior hypospadias (70% Cases):** The meatus is located at midshaft or distal shaft. Most common form is subcoronal hypospadias. They are usually isolated defects. The meatus may seem to open distally, but a length of urethra proximal to the meatus is often hypoplastic (**Fig. 9**). The severity of the defect is judged from the level at which the corpus spongiosum starts deviating on either side, therefore the location of the meatus may not truly reflect the severity.

**Figure 9** Hypospadias. The hooded foreskin has been stretched. The meatus is located distally. Note a visible feeding tube through the distal hypoplastic urethra

- **Posterior hypospadias (30% Cases):** It is a more severe variety with the meatus situated either on the proximal shaft or scrotum or the perineum. Penoscrotal transposition is often associated (**Fig. 10**). Severe hypospadias with undescended testes and/or asymmetric genitalia may be associated with disorders of sexual differentiation (**Fig. 11**).

## Surgery

The aim of hypospadias repair is to reconstruct a penis that is structurally and functionally normal. This can be achieved in most cases through a single stage repair performed at 12–18 months of age. A child born with hypospadias should not be circumcised for religious reasons at birth because the foreskin is used for urethral reconstruction during surgery. Meatal stenosis in hypospadias does not lead to back pressure changes and therefore meatotomy to improve the stream before definitive surgery is unnecessary. Surgery should be completed before the child starts going to school. Parental counseling and alleviating their fears about the child's sexual and married life is also an important aspect of management.

**Figure 10** Proximal hypospadias with penoscrotal transposition. The meatus is midscrotal

**Figure 11** Severe hypospadias with gonadal asymmetry. Such cases need evaluation for disorders of sexual differentiation

## PENILE AGENESIS (APHALLIA)

It is a rare malformation with an incidence of 1 in 10 million. Early insult to the developing genital tubercle is the cause. The scrotum and both testes are normal, but the phallus is not formed at all (**Fig. 12**). The urethra opens in the perineum or within the anal verge. The child is continent. It is a distressing condition for the family with parental concern regarding sex of rearing and child's body image. Generally, there is no urinary obstruction. The child should be reared as a male because of the hormonal milieu being testosterone dominated—their testes are normal. Several techniques are there to reconstruct the urethra and the phallus.

## MICROPHALLUS

Normal stretched penile length in a term neonate is 3–3.5 cm. If it is less than 2.5 cm, it is termed as microphallus. The corporal bodies are less developed. The urethra and bladder are normal. Testosterone assay should be done. If the level of testosterone is subnormal, topical or systemic testosterone should be given. Primary microphallus with normal hormones does not respond to testosterone.

## PRUNE BELLY SYNDROME

Congenital prune belly syndrome is characterized by a typical wrinkled abdominal wall (**Fig. 13**), deficient abdominal muscles, generalized dilatation of the upper and lower urinary tract and bilateral abdominal testes. The bladder is typically large and the posterior urethra is dilated. Problems arise because of functional urinary tract obstruction and stasis of urine leading to high propensity for urinary tract infections. Occasionally, anorectal malformation may be associated. The severity may vary with a wide spectrum. Management in the newborn period is generally conservative. Vesicostomy may be needed to facilitate urinary drainage. Urethral catheterization is often difficult in these babies because of an abnormal and hypoplastic posterior urethra and therefore anticipatory catheterization should not be done. Abdominoplasty is usually carried out at 1–2 years of age. Some surgeons advocate early major urinary and abdominal wall reconstruction.

## FEMALE GENITAL MALFORMATIONS

### Congenital Ovarian Cyst

It is not unusual to pick up a cyst in the abdomen of a female fetus on antenatal ultrasound. The most common reason for this is an

**Figure 13** Prune belly syndrome. Bilateral kidney masses are visible. Abdominal wall is wrinkled and lax

ovarian cyst. It should be confirmed by a postnatal scan. Size and symptoms determine the management. Most cysts which are less than 4 cm and asymptomatic are managed expectantly with serial ultrasound. They tend to resolve with time. If they are big or do not resolve with time, laparoscopy should be carried out at few months. The cyst may be aspirated or excised. The aim is to preserve normal ovarian tissue. Occasionally, the cyst is found to be tortuous, in this case it is best excised. Neonatal cystic torsion may be asymptomatic. Occasionally, an asymptomatic cyst of ovarian origin lies high in the subhepatic region mimicking a choledochal cyst. Laparoscopy provides good diagnostic and therapeutic tool in such cases.

### Mass at Vulva

A mass at vulva could be imperforate hymen causing distended vagina (**Fig. 14**). The vaginal secretions in response to maternal estrogens accumulate behind the hymen. Very large vagina may press on the urethra and bladder neck causing urethral obstruction. Treatment is fenestration of the hymen.

Urethral polyp (**Fig. 15**) and prolapsing ureterocele could also present as a vulval mass. A special variety of ureterocele (cecoureterocele) may have a urethral extension. They usually cause significant urinary obstruction and require surgery rather urgently.

**Figure 12** Aphallia. Testes and scrotum are normal. Urethra opens in the anal canal

**Figure 14** Imperforate hymen. Note the bulging hymen due to a distended vagina

**Figure 15** Urethral polyp. The polyp has been pulled out in preparation for excision. Note absence of anal opening

### Urogenital Sinus and Cloacal Malformations

Abnormalities of the vagina, uterus and urogenital sinus (UGS) are common with or without anorectal malformations in a female. They may consist of duplication anomalies—bifid vagina, septate vagina, uterus didelphus and bicornuate uterus. UGS is characterized by a common channel into which the urethra and the vagina open. The length of the common channel may vary. Isolated UGS malformations seldom cause symptoms and do not warrant neonatal treatment. Ultrasound evaluation of the urinary tract should be done to exclude obstructive uropathy, which may be seen in high UGS.

Cloacal malformation, in which the hind gut, the vagina and the urethra drain through a common single channel, is a severe anomaly that requires urgent evaluation of the urinary tract. The patient may have palpable vagina in the lower abdomen because of distal obstruction resulting in hydrocolpos. It can compress the bladder neck causing urinary obstruction. Besides making a colostomy, urgent decompression of the urinary tract and vagina may also be needed in the form of vesicostomy or vaginostomy. A more detailed description of cloaca is given with gastrointestinal malformations.

### Vaginal Atresia (Mayer-Rokitansky-Küster-Hauser Syndrome)

A defect in the formation, differentiation and fusion of the paramesonephric (Müllerian) ducts may result in a spectrum of anomalies of Müllerian agenesis. Typically the vagina, uterus and the fallopian tubes are absent. The lower vagina, which is of UGS origin, may remain as a dimple in the vulva. The ovaries are normal. Diagnosis is usually made either incidentally or near puberty because of primary amenorrhea. In females born with anorectal malformation, wherein there are two openings in the vulva—thought to be having rectovaginal fistula, should be suspected as having anovestibular fistula with vaginal atresia until investigations reveal normal Müllerian development. Many associated malformations have been described including vertebral and ear anomalies. Several techniques of vaginal reconstruction from skin and bowel are described.

### POSTERIOR URETHRAL VALVES

Posterior urethral valve is the most common obstructive uropathy of the lower urinary tract in a male neonate. There is an obstructing

membrane at the distal end of posterior urethra. This leads to upstream back pressure changes in the form of bladder neck hypertrophy, bladder trabeculations and hydroureteronephrosis. Besides urethral obstruction, the key factors contributing to the overall morbidity are: bladder dysfunction, functional ureteric obstruction and varying degrees of genetically determined renal dysplasia. Antenatal diagnosis on ultrasound is suggested by bilateral upper tract dilatation, distended bladder and dilated posterior urethra. The bladder neck is hypertrophied giving rise to a constriction between the bladder and the posterior urethra (keyhole sign). The bladder may not empty well leading to oligohydramnios. PUV is a wide spectrum disease varying from mild abnormality—late antenatal diagnosis, no oligohydramnios, mild hydronephrosis to severe disease—early fetal abnormality, oligohydramnios, echogenic kidneys, severe hydroureteronephrosis.

Clinical picture at birth can also vary. The child may be completely asymptomatic or may have poor urinary stream. Severe cases present with sepsis, azotemia, dyselectrolytemia and acidosis. A hypertrophied bladder is usually palpable even after micturition. Kidneys may also be palpable. If oligohydramnios was significant, the child may have respiratory distress (lung hypoplasia) and limb compression effects. The diagnosis should be confirmed by postnatal ultrasound and MCUG (**Fig. 16**).

### Treatment in Neonates

- *Baby well at birth, no oligohydramnios, and normal kidneys, baby feeding well and passing urine:* It indicates mild end of the spectrum. Prophylactic antibiotic is started. The child should be scheduled for surgery electively within a few days for an on table MCUG, primary endoscopic valve ablation and circumcision. Postoperatively urinary catheter is kept for 48 hours. Oxybutynin is started to relax a hypertrophied bladder. Check endoscopy should be performed after 3–4 months to confirm completion of valve ablation. Follow-up should be done jointly with a pediatric nephrologist and is aimed at evaluating bladder function, monitoring renal chemistry and management of chronic renal disease.
- *More severe disease [bilateral hydroureteronephrosis (HUN), kidneys dilated], child not passing urine well:* The child should

**Figure 16** MCUG in a case of PUV. Note hypertrophied bladder neck (white arrow) and dilated posterior urethra (black arrow). The bladder is trabeculated and there is severe reflux on the left. This is called VURD. The left kidney is dysplastic. This is a pop off mechanism to safeguard the other kidney  
*Abbreviations:* MCUG, micturating cystourethrogram; PUV, posterior urethral valve; VURD, valves with unilateral reflux dysplasia.

be catheterized with a silastic catheter. If the catheter drains well and the upper tracts decompress on ultrasound, primary valve ablation is carried out after few days. If appropriate equipment is not available, a vesicostomy may be considered followed by endoscopic valve ablation after few months. If the response to catheter is not good, high diversion (ureterostomy or pyelostomy) should be done. While doing ureterostomy often the kidneys are found dysplastic as evidenced by lobulations, and sometimes, cystic changes on the surface (**Fig. 17**). Valve ablation and ureterostomy closure is usually done at 1 year.

**Figure 17** Posterior urethral valve (PUV). There was no response to catheter drainage. Operative exposure for ureterostomy shows dilated and tortuous ureter and small dysplastic lobulated kidney. Note multiple cysts on the surface of the kidney

### Fluid and Electrolyte Management

Post obstructive diuresis can cause severe dehydration, hyponatremia and acidosis. A careful watch on the urinary output and electrolytes is mandatory. High sodium and fluid volumes are needed to offset the diuretic effect. Blood gas analysis should be repeated frequently to assess and treat acidosis. Many patients require long-term therapy with sodium bicarbonate.

## ANTENATAL HYDRONEPHROSIS

Unilateral hydronephrosis is the most common genitourinary abnormality detected on antenatal ultrasound. It leads to frequent in utero referral for parental counseling and prognostication. Although in nearly two-thirds cases it is caused by nonobstructive dilatation, which does not need any surgery, it is important to evaluate all cases to identify the one-third that are truly obstructive—needing surgical correction. Antenatal scan should aim to identify and measure the anteroposterior (AP) diameter of the pelvis, renal size, echogenicity, ureteric dilatation if any, bladder characteristics—filling and emptying, bladder wall thickness and dilatation of the posterior urethra. Ureteric dilation is nearly always pathological, it may be due to PUV, vesicoureteric reflux (VUR) or vesicoureteric junction obstruction (VUJO).

The differential diagnoses of antenatal hydronephrosis are:

- Unilateral hydronephrosis, no ureteric dilatation, bladder normal: *Nonobstructive dilatation, PUJO.*
- Unilateral hydroureteronephrosis, normal bladder: *VUR, VUJO*
- Unilateral or bilateral hydroureteronephrosis, thick bladder, full bladder not emptying well: *PUV*

- Bilateral hydronephrosis, no ureteric dilatation, bladder normal: *Bilateral PUJO, bilateral nonobstructive dilatation.*

## How to Differentiate Between Obstructive and Nonobstructive Unilateral Hydronephrosis

### Antenatal History and Progression of Dilatation

There is a direct correlation between AP diameter of the renal pelvis and probability of obstruction. If the AP diameter is above 50 mm, there is almost 100% chance of the baby needing surgery soon after birth. An AP diameter of 10 mm or less is associated with only 10% risk of obstruction. Antenatal onset and progression is also important. An abnormality picked up early at 18–20 weeks, which is progressive, is more likely to be obstructive than a nonprogressive dilatation picked up late in second or third trimester.

### Postnatal Ultrasound

The baby is usually well at birth. The progression of hydronephrosis should be checked by ultrasound performed at 1 week, 2 weeks and then every 3 months. A progressive dilatation indicates obstructive lesion. Nonobstructive dilatation tends to resolve with time. Progressive hydronephrosis with decreasing parenchymal thickness is almost always obstructive.

### Radionuclide Imaging

At 4 weeks, the kidneys are mature enough to handle radionuclide imaging agents. A radionuclide renogram performed with DTPA (diethylenetriaminepentaacetic acid)/MAG (mercaptoacetyl triglycerine) III/EC (ethyl cysteine) tells about excreting capacity, differential function and the pattern of pelvic clearance. The time activity curve indicates whether the drainage is normal or obstructive or equivocal. Equivocal cases can be resolved by adding diuretic. If the clearance follows a diuretic, it is nonobstructive—equivocal curve was because of reservoir effect of a dilated pelvis. Persistent obstruction despite diuretic indicates obstructive PUJO.

### Intravenous Urogram

Advent of radionuclide imaging has led to less frequent use of IVU. But it provides good anatomical details. It is especially useful in duplex systems with PUJO in one moiety (**Fig. 3**).

## Bilateral Upper Tract Dilatation without Ureteric Dilatation on Antenatal Scan

Bilateral PUJO can occur in 20% cases. Ureteric dilatation must be looked for very diligently to exclude lower urinary tract abnormality such as VUR and PUV. The baby should be put on prophylactic antibiotic. MCUG is done to exclude reflux and PUV. Early diuretic renogram with MAG III should be done and if PUJO confirmed, early surgery should be performed.

## HYDROCELE, HERNIA, UNDESCENDED TESTIS

These entities are described together because of a common embryological basis. The testis develops in the lumbar region but descends to the deep inguinal ring by 12 weeks. During the inguinal phase of its descent at 25–30 weeks, the testis carries a peritoneal diverticulum (processus vaginalis) with it, which obliterates later. Failure of obliteration of the processus vaginalis may cause hernia, hydrocele and encysted hydrocele of the cord. If the processus is narrow, allowing only peritoneal fluid to pass through, a hydrocele results. If it is wide enough to allow intestinal loops or omentum to pass through, a hernia results. The testis may remain undescended anywhere along the path of normal descent depending upon the timing of embryonic event leading to arrested descent. Occasionally, it may deviate from its normal path after exiting the superficial ring to lodge itself at ectopic location such as parascrotal and suprapubic.

## Hydrocele (Fig. 18)

A hydrocele is a collection of fluid between the layers of the tunica vaginalis, which communicates with the peritoneal cavity through a patent processus vaginalis. It is common in the first few months of life but resolves by the end of first year as the processus obliterates. Usually the swelling progresses during the day when the child is active. During sleep some fluid from the hydrocele seeps back into the peritoneal cavity making the swelling smaller. The swelling is painless, is situated around the testis, is brightly transilluminant, has no crying impulse and it cannot be emptied by pressure because of an ink-well effect. The underlying testis may be palpable when the hydrocele is lax. The upper limit of the hydrocele is clearly demonstrable—a finding used to distinguish it from a hernia. Most hydroceles disappear by the age of 1 year and surgery is only required if the hydrocele persists beyond 2 years.

**Figure 18** Right hydrocele. Note the scrotal swelling

## Inguinal Hernia

Indirect inguinal hernia is a common condition in children with an incidence of 0.8–1.4%. It is five times more common in males. Sixty percent occur on right side, 30% on left and 10% are bilateral. The incidence is higher in premature babies (30%). It presents as an intermittent inguinal or inguinoscrotal swelling, which enlarges with straining and reduces at rest. There is a characteristic crying impulse. The upper margin of the swelling cannot be reached. The swelling is reducible.

Treatment is herniotomy which should be performed electively soon after diagnosis. Waiting for too long (for the child to grow) is not advisable as the chances of obstruction and incarceration are high during infancy. Surgery should be performed under general anesthesia by a trained pediatric surgeon under magnified vision. Neonatal and infantile herniotomy is a very delicate operation with 1% risk of damage to vas and vessels leading to testicular atrophy. The operation can be performed through an open inguinal incision or laparoscopic approach. Premature babies who develop hernia in the neonatal unit should be operated when their medical condition is satisfactory and they are otherwise ready to be discharged.

Complications in form of irreducibility, incarceration and obstruction are common during infancy. Hence, there should not be any inordinate delay in surgery when a hernia is diagnosed. If the child presents with an irreducible hernia but is otherwise stable with no hemodynamic disturbances, a gentle attempt at manual reduction (taxis) under sedation may be given. If successful, herniotomy should be performed after 24–48 hours. If unsuccessful, emergency surgery should be done.

## Obstructed Hernia

The bowel within the sac is obstructed. There are features of intestinal obstruction with a tense, tender and irreducible swelling at the external inguinal ring and no crying impulse. Dilated bowel loops in the abdomen, and at times in the scrotum, are evident on X-ray.

## Strangulation

The vascularity of the herniated bowel is compromised. This can rapidly lead to gangrene of bowel and ischemia to the testis. Child presents with features of toxemia, shock and blood in stools. There is redness and induration over the swelling.

An obstructed or strangulated hernia needs urgent surgery after adequate resuscitation.

## Undescended Testis

Undescended testis (UDT) results when its descent gets halted somewhere along the path of normal descent. The incidence is about 4% at birth in term neonates and 20% in the premature. The incidence is also higher in low birthweight babies. It is more common on the right side. Up to 25% cases have bilateral UDT. A patent processus vaginalis is almost always associated with UDT and in some it may show as a clinically appreciable hernia. However, such hernias are usually wide necked and are unlikely to obstruct and strangulate.

An UDT staying outside the scrotum is exposed to temperature related damage to the germ cells. The scrotal temperature is generally from 1.5° to 2° lower than the abdomen. Seminiferous tubules suffer degenerative changes if exposed to higher temperature beyond 6 to 9 months of life. Leydig cells are not affected as much.

Clinically, UDT can be divided into *palpable* (80%) and *impalpable* (20%). Palpable testis may be felt along the inguinal canal, at the superficial ring or in the superficial inguinal pouch. Differential diagnosis of impalpable testis is:

- Abdominal testis (most common)
- Vanished testis that results from an intrauterine vascular accident
- Testicular agenesis (very rare)
- Inguinal testis in an obese child. The testis is difficult to palpate through fat.

The testis is examined in warm and relaxed surroundings in supine, frog-leg or squatting position. If the testis is not felt easily, it is gently *milked* down the inguinal canal to make it emerge from the inguinal canal, when it can be grasped. In most cases of palpable UDT, it can be easily felt above the scrotum. Retractable testis can be brought down to the scrotum without tension on the chord and it stays in the scrotum for some time on releasing it from the fingers' grip.

Investigations such as ultrasound and MRI to locate the testis are unnecessary. A palpable testis is best treated by orchidopexy through an inguinal incision. If the testis is clinically impalpable, the child should be posted for laparoscopy. Under anesthesia examination is repeated. If the testis becomes palpable under anesthesia, inguinal orchidopexy should be carried out. If it still remains impalpable, laparoscopy is performed to locate and bring the testis down. There is little role for hormonal treatment of undescended testes. At times, it can help increase the girth of vessels to facilitate surgery. Another possible use of hormones is to differentiate between true UDT and retractile testis.

Orchidopexy for congenital cryptorchidism is recommended at 6–12 months of age since degeneration of spermatocytes starts at 6 months of age and is nearly complete by 2 years. Other problems that can occur with UDT (hence the reason for surgery) are: increased risk of torsion, higher chances of malignancy especially

in intra-abdominal testis, decreased fertility potential related to thermal injury and increased risk of trauma to UDT.

### Retractile Testis

The retractile testis is a normal size testis which although normally descended, usually lies near the neck of scrotum because of an increased cremasteric activity. The testis is present in the scrotum on some occasions such as during a warm bath or sleep. It can be easily manipulated to the bottom of the scrotum and stays there for some time. In contrast, a truly UDT springs back immediately to its original position. With retractile testis, the ipsilateral scrotum is fully developed.

### IN A NUTSHELL

1. Antenatal ultrasound has had a huge impact on the early diagnosis and management of obstructive uropathy in children. Antenatal unilateral hydronephrosis should not be a reason for medical termination of pregnancy.
2. Most important differential diagnosis of bilateral antenatal hydronephrosis is PUV.
3. Differentiation between obstructive and nonobstructive dilatation of PUJ can be made by radionuclide renal dynamic scan. Early diagnosis and surgery for PUJ obstruction is important to prevent renal damage.
4. PUV, a common obstructive uropathy in males, present in a wide spectrum; normal asymptomatic neonate to very sick uremic and septic neonate.
5. Cystoscopic primary valve ablation is the best treatment for neonatal valves. Yet urinary diversion in the form of vesicostomy or ureterostomy may be lifesaving in certain situations.
6. An inguinal hernia in an infant should be surgically treated sooner. Delay may lead to obstruction and strangulation.
7. A hydrocele should be observed for 1–2 years for spontaneous regression.
8. Incidence of hypospadias is increasing because of environmental androgen disruptors and increasing genetic pool.
9. Surgery for hypospadias should be done between 6 months and 18 months of age.
10. Undescended testes are prone to trauma, torsion and temperature related damage to the germ cells. Impalpable abdominal testes may have higher incidence of testicular malignancy. Orchidopexy should be performed at 6 months to 1 year of age to prevent germ cell damage.

## Chapter 18.5

# CNS Malformations

Nidhi Sugandhi, Veereshwar Bhatnagar

Congenital central nervous system (CNS) malformations are one of the most common and debilitating congenital anomalies reported. They result in significant fetal wastage, neonatal deaths and long-term morbidity. Though decreasing in incidence due to meticulous prenatal care and antenatal detection, they still present a formidable challenge in terms of treatment and ensuring a good quality of life to these patients. The most common CNS malformations are neural tube defects (NTDs), spina bifida occulta and aperta (45%), followed by hydrocephalus (12%).

## EPIDEMIOLOGY

The incidence varies widely from less than 1 per 1000 livebirths in developed nations like Western Europe and USA to 5–12 per 1000 livebirths in under developed and developing nations, particularly in Africa, UAE and some pockets of Southeast Asia. These figures do not take into account the large number of spontaneous abortions, still births and increasing number of terminated pregnancies which would make the figures much higher.

The incidence of these malformations has been declining with time in concordance with socioeconomic development and improvement in maternal nutrition and prenatal care. In the 1970s–1980s the incidence was routinely reported to be 5–10 per 1000 livebirths. Presently the incidence has fallen to as low as 0.5 per 1000 livebirths in certain developed countries. This corresponds to the mass programs of screening, nutritional fortification and preconceptional counseling. However, increase in the rate of prenatal diagnosis and increased elective termination of pregnancies may also have some role to play in these statistics.

## EMBRYOLOGY

Understanding the various stages of development provides an insight into the malformations developing at each stage. The development of central nervous system begins at third week of gestation by strictly coordinated cellular interactions.

## Induction and Neural Tube Formation (Neurulation)

At the three layer stage of the embryo, the mesoderm (inducer) initiates the overlying ectoderm to proliferate and form a thickened plate of tissue called as the *Neural Plate* on the dorsum of the embryo. Further proliferation of this plate leads to formation of *Neural Folds* by the upturning of the lateral edges around a linear depression in the center, the *Neural Groove*. The neural folds finally fuse in the midline giving rise to the *Neural Crest*. The neural crest is a site of development of highly specialized neurons which migrate all over the developing embryo and form the peripheral nervous system and its derivatives. The fusion of neural folds begins in the cervical region and proceeds cranially and caudally except at two extreme ends called as the *Cranial and Caudal Neuropores* that continue to communicate with the overlying amniotic cavity for some more time before finally closing by the 25th–28th day of gestation (**Figs 1A to G**). Failure of fusion of these neural folds is responsible for the NTDs.

## Regionalization

Signaling molecules secreted by structures adjacent to the neural tube activate certain genes (sonic hedgehog, homeobox genes)

responsible for formation of a cranio-caudal and dorso-ventral axis of the CNS. The forebrain, midbrain and hind brain develop at the cranial end and the spinal cord at the caudal end of the axis. Similarly different populations of cells (neural crest, sensory, interneurons, glial and motor neurons) occupy specific regions of the dorso-ventral axis. Abnormalities in ventral induction cause malformations of the brain and facial structures such as holoprosencephaly.

## Proliferation and Migration

The neuronal stem cells in the central neural tube proliferate, differentiate and migrate to their particular locations to form the various layers of the cortex, medulla and spinal cord. Incongruities at this stage lead to the disorders of proliferation and organization such as agenesis, lissencephaly, etc.

## Connection and Organization

This refers to the final stage of establishment of neural pathways through synapse formation and axon growth. This is a poorly understood process and is more likely to cause functional defects rather than gross malformations.

## ETIOPATHOGENESIS

Central nervous system malformations are multifactorial and result from complex interactions between environmental, genetic and nutritional factors (**Box 1**).

### BOX 1 Etiology of CNS malformations

- Nutritional
  - Folic acid deficiency
  - Vitamin B<sub>12</sub> deficiency
  - Zinc deficiency
  - Hypervitaminosis A
- Metabolic
  - Maternal diabetes mellitus
  - Homocystinemia
  - Abnormalities of cholesterol metabolism
- Drugs
  - Trimethoprim
  - Triamterene
  - Carbamazepine
  - Phenytoin
  - Phenobarbitone
- Genetic
  - Mutations in signaling pathways: *HOX* gene, *SHH* gene
  - Mutations in 1 carbon metabolism
  - Trisomies 13, 18, 21
  - Consanguinity
- Others
  - Radiation exposure
  - Hyperthermia.

Folic acid and vitamin B<sub>12</sub> (methylcobalamine) have well delineated roles in the cellular interactions and signaling pathways, especially in 1-carbon metabolism which contributes significantly in DNA synthesis. Deficiency of folic acid during the crucial organogenesis phase in the first trimester results in anomalies of closure of neural tube and is responsible for the majority of NTDs. Despite adequate supplementation, 30% NTDs may still occur. These are believed to be due to genetic factors. Nonsyndromic familial NTDs occur due to mutations in genes involved in 1-carbon metabolism such as *MTHFR* gene (methyl tetra hydro folate reductase). Mutations in genes responsible for signaling during organogenesis such as homeobox (*HOX*) and sonic hedgehog (*SHH*) genes also cause CNS malformation in addition to a spectrum of other congenital malformations.

**Figures 1A to G** Line diagrams showing the normal and abnormal development of the central nervous system and in particular the spinal cord. (A) Neurulation at day 18 of embryonic life; (B) Fusing neural folds to form neural tube at day 22; (C) Transverse section through normal spinal cord; (D) Transverse section showing meningocele; (E) Spina bifida occulta; (F) Meningomyelocele; (G) Transverse section of Rachischisis

Most of these mutations are autosomal recessive. The risk of recurrence of a NTD in a sibling is 3–4% after one affected child and increases to 10% after two affected children. Syndromic malformations occur due to specific defects, e.g. defective cholesterol biosynthesis leads to holoprosencephaly in Smith-Lemli-Opitz syndrome.

Maternal intake of drugs interfering with folic acid metabolism such as trimethoprim, triamterene, carbamazepine, phenytoin, phenobarbitone increases the risk of NTDs, as does alcohol abuse, which selectively destroys the midline neural cells. Hypervitaminosis A, radiation exposure, maternal diabetes mellitus and hyperthermia are other teratogens implicated in NTDs. Fetal infection by toxoplasmosis, cytomegalovirus, and rubella can also lead to these malformations. Consanguinity has a definite role to play in syndromic CNS malformations with one series reporting 12 out of 13 syndromic CNS malformations to be a product of consanguineous marriages.

## INVESTIGATIONS (BOX 2)

### Antenatal Diagnosis

#### *Maternal Serum Alpha Fetoprotein (MSAFP)*

Open NTDs lead to a leak of fetal substances into the amniotic fluid and thence into maternal blood. Alpha fetoprotein (AFP) is one such glycoprotein produced in the fetal liver which escapes through the open neural tube into the amniotic fluid and maternal serum. An increased level of AFP in maternal serum at 16–18 weeks of gestation is a sensitive indicator of CNS malformations. A value greater than 2.5 times has a sensitivity of over 90% for anencephaly and 80% for other NTDs. However, MSAFP may be raised in other fetal disorders also such as abdominal wall defects and thus is nonspecific and requires further confirmation. Several countries recommend MSAFP as a screening test for fetal NTDs in all pregnant women.

#### BOX 2 Investigations for CNS malformations

- Antenatal
  - MSAFP
  - Amniotic fluid acetylcholinesterase
  - Ultrasonography
  - Chorionic villus sampling
- Postnatal
  - CECT/MRI of the head/spinal cord
  - USG cranium
  - Muscle charting
  - Urological investigations- USG KUB, MCU, DMSA, DTPA, GFR and UDS
  - X-ray/CT of lower limb anomalies
  - Neurodevelopmental assessment.

#### *Ultrasonography*

High resolution antenatal ultrasound scan can pick up gross CNS malformations such as anencephaly from as early as 12 weeks of gestation and NTDs by 16–20 weeks. However, small NTDs especially in L5-S2 region may be missed on an USG. Thus, this test should be interpreted in conjunction with other markers like MSAFP and amniotic fluid acetylcholinesterase.

#### *Amniotic Fluid Acetylcholinesterase*

Similar to AFP, open NTDs lead to leak of acetyl cholinesterase into the amniotic fluid and can be detected by amniocentesis after 14 weeks of gestation. It is more sensitive and specific as compared to MSAFP (98–99% sensitivity and > 90% specificity) and is usually not markedly raised in other fetal anomalies as abdominal wall defects. However, this is an invasive procedure and fraught with risks.

#### *Chorionic Villi Sampling*

This can be used to diagnose specific known mutations in fetal cells such as MTHFR gene polymorphism in case of familial history of malformations. However this is invasive and carries a risk of fetal loss, hence is used in very selective cases.

### Postnatal Diagnosis

The common CNS malformations such as NTDs and anencephaly are grossly visible in a neonate and require no specific investigations for diagnosis. Investigations are however required to seek associated anomalies (such as cardiac and genitourinary) and for long-term management of functional losses such as for neurogenic bladder and paraplegia. CECT and MRI are good investigations to delineate most of the malformations of the CNS. USG of the head gives useful information in neonates and infants until the anterior fontanel closes. Coupled with a Doppler to assess the cerebral blood flow and resistive index, this can be a very convenient investigation to monitor hydrocephalus. It is also important to routinely screen for associated cardiac and renal anomalies with echo and urinary tract imaging. Radiological and functional assessment of associated lower limb anomalies like CTEV is required. Muscle charting for assessment of power in different muscle groups of the limbs should be done before the surgical repair of the NTDs. Investigations for assessment of vision and hearing is also indicated.

## CLASSIFICATION

CNS malformations have been classified in a variety of ways. The easiest to remember is the one based on the developmental stages at which the malformations occur and their mechanism of pathogenesis (**Box 3**).

## DISORDERS OF STRUCTURE

### **Neural Tube Defects**

Neural tube defects are the most common congenital CNS malformations. They result due to defective neurulation and improper closure of the neural tube. Spina Bifida is a general term which denotes splitting of vertebral arches in the midline, which may or may not be associated with underlying neural tissue defects. There are two types of NTDs, open and closed based on the presence or absence of exposed neural tissue (**Box 4**). In open NTDs the neural tube does not close and the overlying vertebrae, muscles and skin are absent, thus exposing the neural tissue to the environment. In closed NTDs, the overlying skin is intact even though there may be an abnormality in the neural tube or the overlying bones or membranes.

**BOX 3 Classification of CNS malformations**

- **Nonsyndromic**
  - Disorders of structure
    - Neural tube defects
      - Spina bifida
      - Encephelocele
      - Exencephaly and anencephaly
    - Hydrocephalus
    - Arachnoid cysts
    - Arnold Chiari malformations
    - Dandy Walker malformation
    - Craniosynostosis
  - Disorders of segmentation and regionalization
    - Holoprosencephaly
  - Disorders of proliferation
    - Microcephaly
    - Agenesis of corpus callosum
    - Agenesis of cranial nerves
  - Disorders of neuronal migration
    - Lissencephaly
    - Schizencephaly
    - Porencephaly
  - Vascular malformations
- **Syndromic**
  - Von-Hippel-Lindau syndrome
  - Sturge Weber syndrome
  - Osler-Weber-Rendau syndrome
  - Ataxia-telangiectasia
  - Smith-Lemli-Opitz syndrome
  - Cobb syndrome.

**Anencephaly**

When the cranial end of the neural tube fails to close, the developing cerebral hemispheres herniate into the amniotic cavity, a condition called *exencephaly*. Continuous exposure of the developing tissue to amniotic fluid leads to degeneration of the tissue and disappearance of the forebrain. The child is born with absent cerebral hemispheres as well as absent cranial vault with the rudimentary tissue protruding freely from the base of the skull. This is not compatible with life and most fetuses affected with this undergo spontaneous abortions or intrauterine deaths. If detected before 20 weeks with an antenatal USG, the parents may be counseled for elective termination of the pregnancy.

If there is a small defect in the cranial closure of the neural tube, it results in herniation of meninges covered brain tissue from the defect, known as *encephalocele*. The most common site is the occipital region. The herniated tissue is dysplastic and if it contains the hindbrain including the vital respiratory and cardiovascular centers, the survival of the neonate can be difficult. The other common site is the frontonasal region and sometimes these encephaloceles can be mistaken for nasal polyps.

**Spina Bifida**

Meningocele is a sac like protrusion of the meninges containing CSF through a defect in the vertebral arches, muscle and skin. It does not contain any neural tissues and the underlying spinal cord does not enter the sac. When the neural placode or the nerves enter this sac, a *meningomyelocele* is formed. The neural placode at this defect usually consists of an open neural tube and everted central canal covered by the meninges. The exiting motor nerves lie in the wall of this sac. The central canal and the neural tube may reconstitute normally distal to this lesion, but more commonly may have defects like diastematomyelia or syringomyelia. The dural sac is in close apposition with the skin since the muscles and posterior spinous processes are absent (**Figs 2A to C**).

**BOX 4 Types of neural tube defects (NTDs)**

- Open NTDs
    - Anencephaly
    - Meningocele
    - Myelomeningocele
    - Rachischisis
  - Closed NTDs
    - Spina bifida occulta
    - Tethered cord
    - Split cord malformations: Diastematomyelia, Diplomyelia
    - Dermal sinus
    - Intradural lipoma
    - Caudal regression/sacral agenesis.
- } Spina Bifida Aperta

In most severe cases the meningeal sac covering the placode may be absent, leaving the placode, exiting nerves and the central canal fully exposed, called as *rachischisis*. The exposed neural structures suffer from severe damage and thus the fetuses with this condition usually have severe neurological deficiencies.

Frequently, spina bifida aperta is associated with Arnold Chiari malformation and hydrocephalus. This is because the spinal cord is tethered to the vertebral column, and progressive lengthening of the column pulls the cerebrum into the foramen magnum, also hindering the flow of CSF. Even though hydrocephalus may not be evident initially, up to 80–85% of the children will develop this after repair of the meningomyelocele.

Anomalies of the sacrum, anorectal malformations, urogenital system and lower limbs such as CTEV may be present and are caused by involvement of the sacral nerve roots. *Currarino triad* refers to coexistence of NTD (presacral mass), anorectal malformation and sacral anomalies.

Individual NTDs, their clinical features, evaluation, and supportive management are discussed in the chapter on NTDs in Section 42.

**Surgical Intervention**

Early closure of the defect after appropriate investigations and stabilization needs to be planned, unless there are associated conditions increasing the risk of general anesthesia. It is very important to counsel the parents before surgery so that they have realistic expectations about the immediate and long-term results and quality of life. The basic surgical objectives are summarized in **Box 5**. Wound infection and prolonged CSF leak are two common immediate postoperative complications. Long-term complications include development of hydrocephalus, neurogenic bladder and bowel and paraplegia or limb anomalies.

**Closed NTDs**

Presence of closed NTDs may be suggested by cutaneous stigmata like dermal nevus, tuft of hair, hemangiomas, subcutaneous lipoma or a patch of atrophic skin. All of these lesions must be carefully evaluated with MRI to diagnose occult spinal dysraphism (**Figs 3A and B**).

**Neurogenic Bladder and Bowel in Spina Bifida**

Neurogenic bladder and consequent renal dysfunction is the most important determinant of mortality after a successful surgical closure of a NTD. Depending on the level of the lesion, the bladder can either be flaccid (inert) or spastic. A flaccid bladder is seen when the S2-4 nerve roots are affected by lower motor neuron type of pathology. It shows poor detrusor contractions and poor emptying, leading to large amount of stagnant urine and overflow incontinence. A spastic bladder is characterized by uninhibited

**Figures 2A to C** Spina bifida aperta. (A) Meningocele; (B) Meningo-myelocele: 1. Lumbosacral, 2. Thoracic, 3. Cervical; (C) Rachischisis

detrusor contractions and detrusor-sphincter dyssynergia, causing urinary dribbling and ineffectual emptying. Both can lead to infections, increased back pressure, vesicoureteric reflex and renal damage.

Thorough assessment of the urinary system is required including micturating cystourethrogram, nuclear scans of the kidney [diethylene triamine pentacetic acid (DTPA), dimercapto succinic acid (DMSA) and glomerular filtration rate (GFR)] and urodynamic studies. Depending on the pattern of bladder dysfunction, treatment is initiated. Clean intermittent catheterization (CIC) and timed voiding are simple but effective measures to empty an inert

bladder. Drug therapy with anticholinergics is useful to combat the uninhibited detrusor contractions and detrusor-sphincter dyssynergia. Despite all the measures, incontinence may be a huge social and psychological problem. Surgical interventions such as ureteric reimplantation and bladder augmentation are required in the interest of preserving renal function. Still neurogenic dysfunction remains one of the common causes of end stage renal disease all over the world.

Children with NTD may be plagued with constipation or fecal incontinence, further compromising their social integration. An integrated bowel management program including dietary

**Figures 3A and B** Tell-tale signs in spina bifida occulta: (A) Tuft of hair; (B) Dermal sinus

#### BOX 5 Objectives of surgery of neural tube defects

1. Detethering of the neural placode from the meninges and vertebral column, and its tubularization to restore the integrity of the neural tube (spinal cord).
2. Separation of the meningeal sac from the posterior spinal structures and adjacent subcutaneous tissue and closure of the dura in a watertight fashion.
3. Covering of the defect with a fascial or muscle flap.
4. Tension free skin closure with help of rotational or advancement flaps if required.
5. If significant hydrocephalus is present, ventriculoperitoneal shunt may also be performed.

modifications, laxatives, enemas and possibly even antegrade washes from a surgically created stoma can improve the quality of life to some extent.

### Spina Bifida Occulta

This refers to simple vertebral arch defect due to failure of fusion of posterior spinal elements, usually in the lumbosacral region. There are no defects in the meninges, cord or nerve roots. Pure spina bifida occulta is asymptomatic and only detected incidentally. However, it is necessary to rule out neural defects with a MRI as these may require intervention. It should be noted that a diagnosis of spina bifida occulta should be made very carefully before the age of 1 year as the neural arches are not completely fused by then. If underlying neural defects are absent, no intervention is required.

### Tethered Cord

The developing cord initially extends till the sacrum and gradually ascends to its final level of L2 vertebra, due to the differential growth of the cord and the vertebral bodies. In case of tethering, the cord is forcibly fixed at upper sacral vertebrae and its upward migration prevented, leading to severe traction and neurological damage. The traction induced damage progressively worsens with the growth of the vertebral column and with spinal movement. The tethering may be due to a fibrous band, bony or cartilaginous spur or the stalk of a lipoma. It is commonly associated with a thickened fibrous filum.

Isolated tethering is typically diagnosed in toddlers as ambulation worsens the spinal traction and precipitates neurological symptoms like lower limb paresis and bladder/bowel symptoms.

Once diagnosed, it is recommended to perform detethering sooner rather than later as neurological deterioration may be rapid in a growing child.

### Diastematomyelia

Splitting of the cord into two halves, each with a separate dural covering is known as diastematomyelia. In contrast a split cord within a single dural tube is called *Diplomyelia*. The splitting is due to a septum which is ordinarily a bony or cartilaginous spur attached anteriorly to the vertebral body. It may have variable length with the hemi-cords merging into a single entity distal to the spur. One half of the cord may show hypoplasia or dysplasia. The dividing spur needs to be removed surgically if it causes tethering of any part of the hemi-cords.

### Congenital Hydrocephalus

Congenital causes of hydrocephalus are enumerated in **Box 6**. Increased CSF pressure in hydrocephalus compromises the cerebral blood flow leading to retarded growth and atrophy of the brain in severe cases.

#### BOX 6 Congenital causes of hydrocephalus

- *Excess production*
  - Choroid plexus papilloma
- *Obstruction to flow*
  - Atresia/stenosis of Aqueduct of Sylvius/Foramina of Munroe/Magendie or Luschka
  - Arnold-Chiari malformation (with or without NTDs)
  - Dandy-Walker malformation
  - Intracranial cysts: Porencephalic/subarachnoid/colloid cysts
  - Vascular malformations.

### Diagnosis

Macrocephaly occurs before the signs of increased intracranial tension set in. This is accompanied by bulging anterior fontanel, splaying of cranial sutures, thin scalp with distended scalp veins and frontal bossing (**Figs 4A and B**). Increased intracranial tension (ICT) initially manifests as increased irritability, headache, nausea, vomiting, lethargy, impaired upward gaze (setting sun sign), diplopia (sixth nerve palsy) and papilledema. An USG of the head with high resistive index can diagnose hydrocephalus in children with open fontanel.

**Figures 4A and B:** Hydrocephalus: (A) Large head with shiny skin and frontal bossing; (B) CT scan showing dilated lateral ventricles

### *Treatment of Congenital Hydrocephalus*

Treatment of congenital hydrocephalus is mainly surgical and involves correction of the underlying anomaly (for example removal of the secreting papilloma or the obstructive lesion) if possible, and measures to drain the excess CSF. Restoration of the CSF drainage is done by shunting it from an area proximal to the obstruction to a site capable of its reabsorption. The most commonly performed procedures shunt the CSF into the peritoneal cavity (ventriculoperitoneal shunt), pleural cavity (ventriculopleural shunt), atrium (ventriculoatrial shunt) or any hollow viscus such as gallbladder or urinary bladder. Endoscopic third ventriculostomy (ETV) is another option in which a window is created endoscopically between the third ventricle and the basal cisterns, bypassing the aqueduct and the fourth ventricles. This works well in aqueductal stenosis and posterior fossa obstructive lesions.

Nonprogressive hydrocephalus secondary to NTDs may be managed medically after the treatment of the NTD. The CSF production is inhibited by means of carbonic anhydrase inhibitors like acetazolamide and ICT is controlled by osmotic agents like glycerine. This requires close monitoring with readiness to intervene surgically at the earliest indication of increased ICT causing compromised cerebral blood flow and clinical deterioration.

### **Arnold Chiari Malformations**

Chiari malformations refer to a group of similar abnormalities characterized primarily by a hypoplastic posterior fossa and altered structural relationship between the cerebellum, brainstem, spinal cord and the base of the skull. They occur 4 times more frequently in females. The term Arnold Chiari malformation is preferably reserved for Chiari Type II malformation.

#### *Chiari I Malformation*

This is the commonest and mildest of the Chiari malformations and the only one which may be acquired. It is characterized by the herniation of only the cerebral tonsils through the foramen magnum. It may be associated with cervico-thoracic syringomyelia. Hypermobility occipito-atlantal joint in Marfan syndrome or Ehler Danlos syndrome may lead to this malformation.

#### *Chiari II Malformation*

This is seen almost exclusively with NTDs. Both the cerebral tonsils and the brainstem herniate through the foramen magnum. This

is thought to occur due to spinal cord tethering and consequent traction on the posterior fossa structures leading to herniation. It causes obstruction of the flow of CSF from the brain to the spinal cord and therefore leads to hydrocephalus.

#### *Chiari III Malformation*

It causes the most severe neurological deficit and involves herniation of the entire cerebellum and brainstem into the spinal cord. An occipital encephalocele may be an associated pathology.

#### *Chiari IV Malformation*

This is extremely rare and usually incompatible with life. It involves incompletely developed or undeveloped cerebellum with exposed parts of skull and spinal cord.

*Signs and symptoms* are related to cerebellar and brainstem dysfunction and associated hydrocephalus. These include headache, tinnitus, nausea, vertigo, nystagmus, bulbar palsy, impaired muscle coordination, dysautonomic symptoms, syncope and motor weakness. MRI is the best investigation, though CT is most commonly used for diagnosis.

*Treatment* of Chiari malformations is guided by clinical symptoms rather than the radiological findings. It involves decompression of the posterior fossa by laminectomy of the cervical vertebrae and occipital bone flaps. A shunt procedure is usually added for the associated hydrocephalus.

### **Dandy Walker Malformation (DWM)**

This malformation consists of a spectrum of anomalies, resulting from a hypoplastic or absent cerebellar vermis which is replaced by a thin membrane. There is associated obstruction to the fourth ventricle outflow, resulting in hydrocephalus and ballooning of the thin membrane as a posterior fossa cyst. It is usually associated with other anomalies of proliferation and migration including corpus callosum agenesis and lissencephaly. It has also been reported with trisomies 13 and 18 and with maternal warfarin intake. The children may demonstrate a range of symptoms from being totally asymptomatic to being severely debilitated due to hydrocephalus and cerebellar hypoplasia. The affected children show poor motor development, lack of muscle coordination, jerky movements, occipital bulging and lower cranial nerve palsies in addition to signs of raised ICT. MRI is the recommended investigation for diagnosis. Treatment is mainly directed towards relief of hydrocephalus.

## Craniosynostosis

Craniosynostosis refers to premature closure of one or more sutures of the skull. It may be syndromic or isolated. The common syndromes associated with craniosynostosis are enumerated in **Box 7**. The bone is unable to grow in a direction perpendicular to the fused suture and therefore disproportionate growth occurs in a parallel direction leading to characteristic appearance of the head (**Box 8**) (**Figs 5A and B**).

The severity and phenotype of the craniosynostosis depends on the number and the specific suture showing premature fusion. A single prematurely closing suture does not lead to significant functional impairment and surgery may be done only for cosmetic correction. Fusion of multiple sutures results in restricted growth of the brain leading to retarded development and increased ICT. In this case surgery is aimed at excision of the fused suture to allow for the growing brain to expand appropriately. If corrective surgery is carried out before complete growth of the brain (preferably before 2 years), the overall mental development suffers minimally and prognosis is good.

### BOX 7 Common syndromes associated with craniosynostosis

- Apert syndrome
- Crouzon syndrome
- Pfeiffer syndrome
- Jackson-Weiss syndrome
- Muenke syndrome
- Loeys-Dietz syndrome
- Saethre-Chotzen syndrome
- Shprintzen-Goldberg syndrome.

### BOX 8 Prematurely fusing sutures and resultant phenotypes

- Scaphocephaly or Dolicocephaly: Sagittal suture
- Brachycephaly: Bilateral coronal sutures
- Trigonocephaly: Metopic suture
- Plagiocephaly: Unilateral coronal or lambdoid sutures
- Oxycephaly or Turricephaly: Coronal and lambdoid suture
- Kleeblattschädel (cloverleaf skull)/Pansynostosis : Fusion of all the sutures.

## DISORDERS OF REGIONALIZATION

### Holoprosencephaly

Abnormalities of ventral induction in the anterior part of the neural tube lead to malformations of the midline brain and facial structures. This is most commonly due to mutations in sonic hedgehog gene which plays a major role in intercellular signaling and structural induction. It presents as a spectrum of varying severity ranging from isolated olfactory aplasia (arhinencephaly), mild hypotelorism or single central incisor to the most severe malformation where there is failure of the forebrain or prosencephalon to separate into two cerebral hemispheres. In the most severe types the midline intracranial structures are fused leading to a single ventricle, fused basal ganglia and absent falx cerebri. This is associated with fusion of the facial structures in midline, resulting in single eye (cyclopia), single nasal chamber and premaxillary agenesis. The mortality associated with the severe variant is high; however, milder variants may not even be recognized except for cosmetic reasons.

## DISORDERS OF NEURONAL MIGRATION

Migration of neuroblasts begins from the center of the neural tube or the ventricular region. The glioblasts and their axons provide the scaffolding which directs the developing neurons to the right position in the cerebral cortex leading to organization of a six layer cortex. Disorders of migration can be diffuse or focal. The failure of migration may occur due to lack of initiation or arrest of migration anywhere along the path, giving rise to heterotopic tissue rests. No cure can be offered for gross structural anomalies, however symptomatic heterotopic cell rests may be managed symptomatically or even offered surgery.

Lissencephaly (agyria-pachgyria), schizencephaly (presence of clefts), and porencephaly (presence of cysts) are the three main malformations in this group. The first two will be described in detail in the Chapter on brain malformations in Section 42. Porencephaly refers to the presence of white matter lined cysts in the brain, communicating with the ventricles or the subarachnoid space. It occurs due to arrest of migration of neurons intended for the area of the cyst. However they should be differentiated from pseudo-porencephalic cysts developing perinatally due to hemorrhage or infarction. True porencephalic cysts have smooth

**Figures 5A and B** Craniosynostosis: (A) Fusion of multiple sutures; (B) Reconstructed 3D image of a CECT scan showing the fusion of the sutures

walls, pericystic polymicrogyria and distorted pattern of gyri. The symptoms depend on the location of the cyst and include mental retardation, spastic hemi or quadriplegia, optic atrophy, seizures and microcephaly.

## DISORDERS OF PROLIFERATION

### Microcephaly

Microcephaly is defined as head circumference less than 3 standard deviations below the mean for that age. It is not a single malformation but a product of arrested proliferation of neurons due to various causes (**Box 9**). It may be accompanied by any of the disorders of migration described above. It may not be purely congenital, and can also occur due to poor brain development during first two years of life.

Microcephaly can be *microcephaly Vera (MV)* which is purely due to nonproliferation of the germinal neuroblasts or *microcephaly with simplified gyral pattern (MSG)* in which hypoplasia is coupled with disordered migration. MV is characterized by thin cortex and scarcity of neurons in layer II and III of the cortex. The children have varying degree of mental retardation but seizures are rare. In contrast MSG is associated with lissencephaly and has a much worse prognosis. Severe mental retardation is accompanied by intractable seizures developing in the neonatal period along with diffuse spasticity.

Serial head circumference measurement along with CT or MRI features of thin cortex and dilated ventricles can confirm microcephaly. It is also important to investigate for any underlying metabolic or genetic cause, if any, to prevent recurrence in the family. Treatment is mainly supportive and includes counseling and special education to help the child integrate into the society in the best possible way.

#### BOX 9 Causes of microcephaly

- Primary (genetic):
  - Trisomies 18, 21
  - Autosomal recessive (Familial)
  - Autosomal dominant mutations
  - Syndromic
    - Cri-du-chat syndrome
    - Cornelia de Lange syndrome
    - Smith-Lemli-Opitz syndrome
- Secondary
  - Maternal alcohol or cocaine abuse
  - Metabolic disorders –phenylketonuria, maternal diabetes
  - TORCH infection
  - Radiation exposure of developing fetus
  - Malnutrition during first two years of life.

## VASCULAR MALFORMATIONS

Vascular malformations of the CNS include arteriovenous malformations (most common), capillary telangiectasias, hemangiomas and aneurysms of the intracerebral vasculature. They represent 5–10% of all intracranial space occupying lesions and are responsible for 30–80% of all intracranial hemorrhages. These cause symptoms due to local mass effect, hemorrhage, perilesional edema and increased ICT. Seizures and headaches are the most common manifestations, but localizing symptoms such as ataxia, visual or speech disturbances are also seen. Spinal vascular malformations can cause cord compression and symptoms of paraplegia. However, a large number of them may not cause any symptoms and may be detected only incidentally. Malformations

of vein of Galen deserve special mention because they manifest soon after birth and cause severe symptoms, especially due to obstructive hydrocephalus.

MR angiography is the diagnostic modality of choice for vascular malformations. Treatment options include focused radiotherapy, endovascular embolization and open surgical excision.

## PROGNOSIS

Despite best efforts, the long-term picture for cure of congenital CNS malformations is not rosy. Most of the malformations like disorders of migration and proliferation cannot be cured. Mental retardation and physical handicaps are often severe. Ensuring an independent self-sustaining existence for many of the patients may be an uphill task. Functional training including speech and auditory therapy, physical rehabilitation and occupational training are some of the means of meaningful integration of these children in the society. Even in the surgically *curable* disorders like NTD, the quality of life is highly compromised due to fecal and urinary incontinence, renal dysfunction, lower limb paraplegia, hydrocephalus with repeated shunt complications, etc. The parents and caretakers of these children suffer from enormous physical, emotional, financial and social trauma.

It is for this reason many parents now opt for termination of pregnancy in case of antenatal diagnosis. The increasing antenatal detection and subsequent termination may be partly responsible for the decreasing incidence of these malformations in live born neonates. What increases the ethical predicament of such a decision both for the doctor and the parents is the fact that no sign or physical finding can accurately predict the extent of the expected physical and mental disability in the child except in a few drastic situations like anencephaly.

The situation is even more difficult after the child is born with an NTD. There is no confusion about need of surgery in a child with minimal or no preexisting neurological deficits. However, in a child with established severe neurological deficits like paraplegia the decision to operate or not is very tough. On one hand it appears unethical to withhold surgery, especially since the survival rate with good surgical care is greater than 90%. On the other hand is the very real possibility of saddling the parents with a child who may have a repaired NTD but cannot walk, has no control on his bowel or bladder, is mentally retarded, requires multiple orthopedic and shunt surgeries and extensive rehabilitation programs, and is probably going to spend all his life in and out of treatment and rehabilitative facilities and still may not be a happy, functional, independent individual. The parents should be honestly counseled about the condition and expected outcome and allowed to have the major role in the decision making. In most centers, children with severe neurological deficits are operated, only if they survive till one month or beyond, for the ease of future nursing care.

## Recent Research

It was observed that the neurological damage worsened with exposure of the neural tissue to amniotic fluid. Management of Meningomyelocele Study (MOMS) was a multicentric prospective trial that compared the neurological outcome after fetal and postnatal repair of NTDs. It was found that in utero repair of NTDs between 19 weeks and 26 weeks of pregnancy improved the motor function and decreased the incidence of hydrocephalus and requirement of shunts at 1 year. However fetal surgery carries the risk of fetal wastage and prematurity and presently can be offered only at selective centers.

### IN A NUTSHELL

1. CNS malformations are one of the commonest individual malformations afflicting neonates, though their incidence is decreasing. Neural tube defects are the most common CNS malformations.
2. Though the etiology is multifactorial, folic acid deficiency is responsible for almost 70% of the NTDs. Genetic, environmental and metabolic factors also contribute.
3. Teratogenic insults during the first 3 months of embryogenesis leads to CNS malformations. The malformations are classified according to the stage of faulty embryogenesis responsible.
4. NTDs have a spectrum of manifestations ranging from defects that can only be detected on MRI to completely exposed spinal cord and central canal with complete neurological deficit below the lesion. Therefore even small midline abnormalities should be investigated thoroughly. The anatomic location and severity of damage to the exposed neural tissue determines the extent of associated neurological deficit.
5. In addition to local treatment of the lesion, complete assessment and treatment of associated disabilities like hydrocephalus, paraplegia and neurogenic bladder, bowel dysfunction is required. Multispecialty coordination with long-term follow-up is essential for good quality of life.
6. Fetal repair of NTDs has shown a decrease in the requirement of shunts and better neurological function according to the MOMS trial results. However intrauterine intervention carries the risk of fetal wastage and prematurity.
7. Folic acid supplementation has been the most effective public health measure to decrease the morbidity from NTDs. Supplementation should begin 3 months before conception and continue through the first trimester to be effective.

### PREVENTION

The best bet to reduce the morbidity from congenital CNS malformation is by preventing them. Periconceptional folic acid intake has been conclusively proven to decrease the incidence of CNS malformations. To be effective folic acid supplementation must begin at least 3 months before conception. The recommended dose is 0.4 mg per day to prevent first occurrence and 4 mg to prevent recurrence in subsequent pregnancies. Many countries have resorted to routine fortification of flour to ensure adequate folic acid supplementation.

# PART V The Childhood Years

## Section 19 GROWTH: NORMAL AND ABNORMAL

Section Editor Anju Seth

### Chapter 19.1

### Normal Growth

Ruchi Mishra, Vandana Jain

*Growth* is the process of increase in size or mass of a living being as a result of increase in size or number of cells and/or increase in the intracellular matrix. The term *development* is used to connote the process of attainment of functional maturity. Growth occurs in an orderly and organized manner from the time of conception till the closure of epiphyses. It is an integral component of childhood and a marker of health. Deviation from the expected pattern of growth, in terms of gain in length, weight and head circumference may be the first indicator of an underlying illness. In this chapter an outline of the physiology and pattern of normal growth from conception to adolescence is presented.

#### FETAL GROWTH

This is the period of maximum growth. At conception, the zygote measures 130  $\mu\text{m}$  in length and 10  $\mu\text{g}$  in weight. It multiplies its length and weight several times to reach the size of 50 cm and 3 kg at term. Normal fetal growth involves an increase in cell number during the earlier part of gestation, followed by an increase in cell size, which becomes dominant after 32 weeks gestation.

#### Phases of Growth

Fetal growth can be broadly divided into four phases according to the rate of growth:

1. *Up to 16 weeks—Slow rate, less than 10 g per week:* The period from conception to 9 weeks of gestation is termed as embryonic period. Implantation begins on the 6th postconceptional day. At this time, the embryo is a spherical mass of cells with a central cavity and is termed as the blastocyst. By the 2nd week, as the implantation completes, the uteroplacental circulation starts developing. At this time, the embryo is bilaminar. By the 3rd week, mesoderm appears along with primitive neural tube and blood vessels. Between 4th week and 9th week, there is growth at the cranial and caudal ends leading to the development of arms and legs. Skeletal muscles and vertebral precursor also appear. Structures of the face and neck differentiate and lens placode appears. There is rapid growth of the brain along with formation of rudimentary organ systems, the heart and gastrointestinal system begin developing at 5th week, while the formation of lungs begins at 8th week. By the end of the embryonic period (9 weeks), the average embryo weighs about 9 g and measures about 5 cm. By the
2. *16–28 weeks—Accelerated rate, approximately 85 g per week:* During this period, there is further growth and maturation of the organ systems. In the lungs, alveoli develop and production of surfactant begins at about 22–24 weeks. Myelination of the nervous system begins around midgestation and continues till around 2 years of age.
3. *28–37 weeks—Maximal rate, nearly 200 g per week:* There is accrual of protein, fat, iron, calcium and phosphorus during this period along with further maturation of organ systems. The weight triples and the length doubles during this period.
4. *37–42 weeks—Decelerated rate, approximately 70 g per week:* The fetus is considered full term beyond 37 completed weeks. There is minimal growth beyond 42 weeks.

#### Physiology of Fetal Growth

Normal growth *in utero* depends on the genetic potential of the fetus modulated by environmental hormonal and other biological factors, including maternal health and nutrition. The primary regulators of fetal growth are nutrition, insulin and insulin-like growth factors (IGFs). A strong correlation exists between maternal height and weight, and birthweight. This is also referred to as maternal constraint, and is important to limit fetal overgrowth to prevent subsequent dystocia, and preserve mother's capacity for future successful pregnancies. Other maternal factors that affect fetal growth include her nutrient intake during pregnancy, anemia, smoking, alcohol consumption, infections and chronic diseases, and pre-eclampsia.

The placenta is a highly efficient multifunctional organ that integrates signals from both mother and fetus to match fetal demand with the maternal substrate supply of nutrients and gases, while ensuring that fetal waste products are transferred back to the mother. The total placental surface area for exchange is 11  $\text{m}^2$  at term. In fetal growth restriction, the placental villus surface area and placental volume are decreased. Several aspects of placental function are critical for human fetal growth and development, including adequate trophoblast invasion, increase in uteroplacental blood flow, transport of glucose and amino acids from mother to fetus, and the production and transfer of growth regulating hormones.

Placental adaptation in early pregnancy can overcome maternal undernutrition so that fetal nutrition is maintained during the phase of rapid growth in late gestation. A classical example of this is the Dutch Famine of 1944–1945. Women who suffered starvation in their third trimester of pregnancy had lower weight of the placentae as well as of the newborns, with placental weight: birthweight ratio comparable to nonstarved women. In contrast, exposure to famine only during first trimester resulted in enhanced

placental weight, with no adverse effect on newborn weight, suggesting that the plasticity of placenta allows it to compensate for some of the environmental stressors in early gestation.

### Hormonal Influence on Intrauterine Growth

The hormones produced by placenta include estrogens and progesterone, human chorionic gonadotropin (hCG), human growth hormone (GH) variant, and human placental lactogen (hPL), besides organ specific hormones, such as, corticotropin releasing hormone (CRH) as well as hepatic and epidermal growth factors.

Among the various endocrine factors controlling growth in intrauterine life, insulin, IGF-1 and IGF-2 are the most important. The fetal pancreas produces *insulin* in response to nutrient supply and this has a direct growth promoting effect. Insulin induces protein synthesis and hepatic glycogen deposition, increases nutrient uptake and utilization and stimulates the lipogenic activity leading to rapid accumulation of adipose tissue mostly during third trimester. Insulin deficiency results in a reduction in fetal growth, while increased fetal insulin production (as occurs in fetal hyperglycemia in diabetic mothers) results in macrosomia.

Early evidence for the role of *IGF-1* and *IGF-2* in fetal growth was mostly associative. Serum IGF-1 levels were lower and GH levels higher in small for gestational age (SGA) newborns as compared to those with normal weight. Mouse models of IGF-1 and IGF-2 deficiency are born small and have the phenotype of intrauterine growth restricted (IUGR) humans, such as, slow postnatal growth and increased insulin resistance. Insulin, placental lactogen, growth factors, nutrient flux and glucose availability control IGF-1 secretion *in utero*. Experimentally, fetal pancreatectomy reduces IGF-1 levels with resultant compromise of fetal growth, and glucose or insulin infusion stimulates growth.

*Glucocorticoids* are essential for the development and maturation of fetal organs before birth. There is a rise in cortisol concentration during late pregnancy that parallels the increased maturity of fetal organs. In human pregnancy, endogenous maternal cortisol concentrations are 5–10 times higher than fetal cortisol concentrations, and this difference is maintained by the presence of 11 $\beta$  hydroxysteroid dehydrogenase 2 (11 $\beta$ -HSD2) in the placenta, which acts as a barrier enzyme to control the passage of cortisol from mother to fetus. Alterations in the activity of the placental 11 $\beta$ -HSD2 barrier, which result in an increase in maternal glucocorticoids crossing to the fetus, may have a deleterious effect on fetal growth and postnatal development.

*Other factors* like epidermal growth factor, fibroblast growth factor and leptin, a hormone produced by adipose tissue, also play a role in fetal growth and nutritional homeostasis. Any damage to the placenta or placental failure due to any cause results in fetal growth restriction, which may be symmetrical, i.e., weight, length and head circumference are all evenly decreased, if it occurs early in pregnancy, or asymmetrical, i.e., predominant effect on weight, if it occurs later in pregnancy.

### THE INFANCY-CHILDHOOD-PUBERTY MODEL OF GROWTH

Human growth curve has been described by various mathematical models. The hormonal regulation of human growth is very well described by the infancy-childhood-puberty (ICP) model proposed by Karlberg et al (Figure 1). It places the assessment of growth in a dynamic context. It presents growth as an additive function of various biological processes. The rapid growth of the first 2–3 years is represented by an exponential curve, which is largely nutrition-dependent. Both over- and undernutrition in this phase have long-term effects. The childhood phase is represented by a second degree polynomial regression. Until 3 years of age,

**Figure 1** The infancy-childhood-puberty (ICP) growth model for height for boys (Karlberg, 1989)

Reproduced with permission from John Wiley and Sons. Copyright© 2008, John Wiley and Sons. Karlberg J. Acta Paediatrica Scand. 1989;350:70-94.

growth is the additive combination of infancy and childhood components. The childhood component is chiefly GH-dependent. The final component of the model deals with puberty, when growth is described by a logistic function dependent on a combination of GH and sex steroids. This is superimposed on the decelerating childhood model which shows that the magnitude of growth spurt of adolescents is inversely related to the age at peak height velocity.

### INFANCY AND EARLY CHILDHOOD

The terminology used for the various phases of childhood growth is presented in **Box 1**.

#### BOX 1 Nomenclature for different age groups

- **Neonate:** From birth till 28 days of life
- **Infant:** Birth to 12 months of life
- **Toddler:** Children between 1 year and 3 years of life
- **Preschooler:** Children between 3 years and 5 years of age
- **School-aged:** Boys 6–12 years, girls 6–10 years
- **Adolescent:** Children between 10 years and 19 years of life.

### The First Year

The first year of life is marked by rapid physical growth, maturation and acquisition of competence. The newborn shows 7–10% decrease in birthweight in the 1st week of life due to loss of excess extravascular fluid and limited intake. Nutrition improves as colostrum is replaced by breastmilk with higher fat content and as the mother and child regularize the feeding process and schedule. Birthweight is again achieved or exceeded by the end of 2nd week of life and the subsequent rate of weight gain is approximately 30 g/day for the first 2 months. This is the period of fastest postnatal growth. Between 3 months and 4 months, weight gain is at the rate of 20 g/day, so that the infants double their body weight by 4–5 months of age. Between 6 months and 12 months, physical growth slows further. By the first birthday, weight is approximately three times the birthweight, head circumference has increased by 10–12 cm, and length by 50% (Table 1).

### The Second Year

The growth rate declines in the 2nd year along with a decline in appetite and increase in physical activity. Children reach half their adult height by the end of 2nd year. Toddlers have a long torso and short limbs with a protruding abdomen. The head circumference also increases as myelination proceeds. Ninety percent of the head

circumference is achieved by the end of 2nd year with an additional 5 cm achieved over the next few years (**Table 1**).

### Preschool Years

During the preschool years (age 3–5 years), the child grows by 6–8 cm/year and gain 2–3 kg weight/year. Weight is four times the birthweight by 2½ years. Many preschool children have physiological pes cavus and genu valgum that correct spontaneously with age. Growth in the first 2–3 years of life is determined predominantly by nutrition, bone metabolism and a normal thyroid function. Nutritional requirements are high during this period as there is rapid somatic growth. Good nutrition involves adequate calorie and protein intake, sufficient micronutrients like iron and zinc and good social stimulation, i.e., happy and encouraging home environment.

About two-thirds of the infants with IUGR show catch-up growth in the first 2 years of life as the growth-restraining intrauterine influences are removed and postnatal nutrition is adequate. On the other hand, inadequate nutritional intake, due to organic or inorganic causes results in growth deceleration, referred to as *failure to thrive*. Growth deceleration is an adaptive response to suboptimal nutrition. Diminished growth brings the nutrient demand into balance with the nutritional intake without adversely affecting the biochemical and functional homeostatic measures.

Sufficient intake of calcium and vitamin D is required for adequate bone turnover. Thyroid hormones are of paramount importance in postnatal growth by having a direct effect on epiphyseal cartilage as well as a permissive effect on growth hormone secretion.

### Growth in Mid-childhood

From 5 years of age until the onset of puberty, linear growth velocity is the slowest (4.5–6 cm/year) and weight gain is approximately 2 kg/year. Growth occurs irregularly in 3–6 timed spurts per year. A growth velocity less than 4.5 cm/year should alert the physician to evaluate for cause of growth retardation. Head circumference increases by 2–3 cm in the entire period.

Growth in mid-childhood is chiefly hormone dependent. GH acting directly, and through IGF-1, is the main growth promoting factor for cell division and growth. GH is produced in a pulsatile manner under the reciprocal influences of growth-hormone-releasing hormone (GHRH) and somatostatin. This balance is maintained by a number of neurotransmitters, neuropeptides, as well as metabolic, neurologic and hormonal influences. Ghrelin, a 28 amino acids or exogenic polypeptide secreted from the oxyntic cells of gastric fundus, also promotes GH release. GH directly stimulates the division of resting chondrocytes in the reserve zone of the cartilage plate, as well as stimulates their secretion of IGF-1. The locally produced IGF-1 exerts paracrine effect on the chondrocytes, resulting in an increase in the number of cells in the proliferation zone, and their differentiation and progression into the hypertrophic zone. IGFs constitute a family of peptides that is partly GH dependent, and mediates many of the anabolic and mitogenic actions of GH. IGF-1 is a 70 amino acid peptide with an approximately 50% homology to insulin. IGF-1 level in newborns is generally 30–50% of adults. There is a gradual rise in serum concentration with age with attainment of adult levels at the onset of puberty. Hepatic IGF-1 circulates almost entirely bound to IGF binding proteins (IGFBPs) with less than 1% being free. IGFBPs control the action of IGF by controlling its storage and release in extracellular matrix. The principal binding protein is IGFBP-3, which binds 75–90% of circulating IGF-1 in a large ternary complex consisting of IGFBP3, IGF-1 molecule and acid labile subunit (ALS).

### Adolescent Growth

Adolescence is the period in human growth and development, from ages 10 years to 19 years, during which there is a gradual attainment of physical, reproductive, social and mental maturity. With the onset of puberty, there is an increase in growth velocity. The peak growth velocity during this period is nearly double the velocity in the prepubertal phase. There is asymmetric pattern in growth with the hands and feet growing first, followed by arms and legs, and finally the trunk and chest.

*Girls* have a peak in growth velocity during early puberty and before menarche, i.e., Tanner stage II–III with a mean velocity of 9 cm/year (range 7–11 cm/year). The appearance of breast buds (age 8–12 years) marks the onset of puberty. Menarche occurs after 2–3 years of onset of puberty (age 9–16 years, median 12 years). There is change in body habitus with female pattern of fat deposition, i.e., around hips and thighs. The adolescent growth spurt lasts for 2.5–3 years, during which the average height gain is 24–26 cm in girls. The average gain in height postmenarche is 6–8 cm, being more in girls who attain menarche at a younger age and lesser in those who attain menarche at an older age.

In *boys*, peak growth typically begins 2–3 years later than girls (at age 12–15 years) and at a later sexual maturity rating (SMR) stage. Boys have peak growth velocity around Tanner stage III–IV during which they have a mean growth velocity of 7–13 cm/year (average 10.3 cm/year). Testicular enlargement marks the beginning of puberty in boys, peak growth occurs when the testicular volume reaches 9–10 mL. The average total growth during the pubertal spurt is 27–30 cm. Boys have longer growth spurt period than girls. Rapid enlargement in the larynx and pharynx leads to voice cracking followed by changes in the voice. There may be considerable variation in these figures depending upon the age at onset of puberty. A kind of compensatory mechanism is seen to occur where individuals with earlier puberty grow less before puberty and more during puberty while those with late pubertal development start their puberty taller but grow less during puberty.

### Physiology of Adolescent Growth Spurt

At puberty the pulsatility and the basal levels of GH secretion increase 2–3 fold, enhanced primarily by estrogen. Along with the increase in estrogen, androgens and GH there is increase in the synthesis of hepatic and chondrocyte IGF-1 resulting in rapid chondrocyte proliferation, thus leading to growth surge.

Estrogen in both boys and girls (through peripheral aromatization of testosterone) brings about epiphyseal maturation, with eventual bony fusion and growth cessation. At low levels, estrogen enhances the growth of chondrocytes in the proliferative zone; while at higher levels, it decreases chondrocyte proliferation, and accelerates maturation, senescence, apoptosis and osteoblastic invasion of the cartilaginous growth plate. Estrogen also enhances the local production of IGF-1 and its receptors directly.

### CHANGE IN BODY PROPORTION

Assessment of body proportion is an important part of the assessment of linear growth in children. Different parts of the skeleton grow at different rates. In the initial phases of growth, upper part of the body (torso and head) are larger, but as the child becomes older, there is greater growth of the extremities, thus changing the upper segment (US) to lower segment (LS) ratio.

Lower segment is the distance between the upper border of pubic symphysis and the floor in a patient who is standing against a vertical board/wall in proper position for height measurement. This reading may be erroneous because it is difficult to palpate the upper border of symphysis pubis, especially in obese children, and is seldom recommended. Sitting height can be taken as a

**Table 1** Rate of growth in terms of weight, length and head circumference from birth to 6 years

Age	Increase in head circumference (cm/month)	Increase in length (cm/month)	Increase in weight
0–3 months	2.0	3.5	30 g/day
3–6 months	1.0	2.0	20 g/day
6–9 months	0.5	1.5	0.5 kg/month
9–12 months	0.5	1.2	0.5 kg/month
1–3 years	0.25	1.0	2 kg/year
4–6 years	1 cm/year	5 cm/year	2 kg/year

surrogate marker of US. This is measured by making the child sit on a horizontal stool with straight edges (square or rectangular stool) of known height against the vertical board. LS can be derived by subtracting the sitting height from the total height.

Upper to lower segment ratio is 1.7:1 at birth and goes on decreasing as the limb length increases to reach 1:1 at 10 years of age and 0.9:1 after the completion of adolescent growth. In precocious puberty, as the bones fuse early the body proportion is childlike (higher US:LS ratio), whereas in hypogonadism, extremities are much longer than the trunk. US:LS ratio is affected in skeletal dysplasia, being higher in short-limbed dysplasias such as achondroplasia, and lower in conditions with short trunk such as spondylo-epiphyseal dysplasia.

Arm span is estimated by making the child stand with outstretched hands against a flat wall with the arms held horizontally to create 90° angle to torso. The fingertip to fingertip distance is measured. Arm span is shorter than the height in boys before the age of 10–11 years and in girls before the age of 11–14 years after which it exceeds the height. In adults, the arm span is greater

than the height by about 5.3 cm in males and 1.2 cm in females. Measurement of arm span is useful in the clinical diagnosis of disproportionate short and tall stature. For example, arm span is increased (compared to height) in Marfan syndrome and decreased in achondroplasia. Arm span is also useful for estimation of height in children with severe spinal deformity or severe cerebral palsy who cannot stand.

### IN A NUTSHELL

1. Growth in children is an important marker of the overall health.
2. Fetal period is the period of maximum growth, modulated by intrinsic fetal factors as well as maternal factors.
3. Growth in infancy and early childhood is driven chiefly by adequate nutritional intake and in mid-childhood by hormonal balance.
4. Adolescence is the next rapid phase of growth during which there is a gradual attainment of physical, reproductive, social and mental maturity. This phase is driven by growth hormone and sex steroids.

## Chapter 19.2

# Factors Affecting Growth

*Devi Dayal, Anil Kumar Bhalla*

Growth in children and adolescents is a dynamic process that may be affected by several factors and still remains remarkably predictable. An understanding of these factors allows pediatricians to timely identify and treat nutritional, chronic systemic and endocrine disorders that have growth deviation as one of the components. Major factors that affect growth in children are described in this chapter.

## HEREDITY AND GENETICS

The genetics of human growth is very complex and all inherited traits have not been identified yet. The growth of a child represents the results of interaction of genetic and environmental forces. Genetic potential as determined from the parents' anthropometry has a direct influence on a child's growth potential and the predicted adult height. The genetic influence on height is usually well established by 2–3 years of age. Assuming the normal process of heredity and almost similar environmental effects on growth in both generations, most children would achieve heights within  $\pm 2$  standard deviation (SD) of their mid-parental height. Height, head size, chest shape, fatty tissue, etc., have better genetic association than other somatic characteristics. The genetic factors also determine the pubertal patterns in children. For example, daughters attain menarche at similar age as their mothers and usually have similar length of menstrual cycle. Mutations of numerous genes encoding proteins that affect multiple pathways of regulation of cell proliferation have been shown to influence growth in children. Various chromosomal abnormalities result in distinct syndromes associated with short stature, e.g., Turner syndrome, Down syndrome and 18q deletion syndrome.

## ETHNICITY

Traditionally, it was believed that different ethnic groups show different patterns of growth. For example, Asian and Chinese population groups are shorter and lighter when compared with Caucasians and African-Caribbean groups who are taller and heavier. However, the recent Multicenter Growth Reference Study (MGRS) by World Health Organization (WHO) showed that variability in infant growth was greater within population groups of similar ethnicity than between the different country groups. It implies that the effect of ethnicity is negligible if other environmental and socioeconomic conditions are similar.

## SEASON AND CLIMATE

About 30% of children show seasonal variations in growth velocity. Height growth is fastest in spring while weight growth is fastest in autumn. The underlying mechanisms for these variations are largely unknown but probably involve variations in hormone secretion. Climate also has a minor effect on overall rate of growth. The racial variations in stature are also believed to be related to the differences in climates.

## SOCIOECONOMIC FACTORS

Children from different socioeconomic strata differ in average body size at all ages. These differences in growth result from factors

like nutrition, regularity of meals, sleep, exercise, frequency of acquiring infections, etc. Economic conditions also influence the secular trends in heights. Children living in average economic conditions have shown approximately 1–2 cm increase in height per decade. Family size also exerts an indirect influence on the rate of growth probably through factors like nutrition, individual care and attention. Psychosocial dwarfing resulting from child abuse/neglect or emotional deprivation is one of the important social causes of growth failure in children. Disturbances of growth hormone (GH) secretion, function of thyroid hormones and insulin-like growth factor-1 (IGF-1) have been noted in children with psychosocial dwarfism.

## ALTITUDE

Various biochemical, physiological and micro-anatomical responses due to fall in partial pressure of oxygen at high altitudes may affect growth of children. Children born at high altitude have lower birthweight probably due to relative intrauterine hypoxia. In general, children at very high altitudes are thinner. However, recent data from Saudi Arabia indicates that hypoxia of the degree found at altitudes of approximately 3,000 m above sea level is not sufficient to adversely affect the growth of children and altitude of this height may be more favorable to growth. Children living at low altitudes were reported to be comparatively thinner probably due to the prevailing tropical environmental conditions at low altitudes in that study.

## MATERNAL FACTORS

Intrauterine growth depends on maternal health and nutrition, the placenta that supplies food and oxygen to the fetus and the fetal genetic information. Conditions like maternal malnutrition, placental abnormalities, high blood pressure/toxemia, diabetes mellitus, infections, uterine malformations, smoking, alcohol or other drugs abuse may affect intrauterine growth. The role of fetal pituitary and thyroid hormones in fetal growth is evolving. Infants with athyreosis and anencephaly have normal size at birth. Fetal pituitary derived GH is now believed to play a small but significant contribution to fetal and immediate postnatal growth.

Weight and fat gain during pregnancy and lactation are also powerful determinants of infant size at birth and during first 6 months. Energy deficits as well as zinc and vitamin B<sub>12</sub> deficiencies in mothers living in less developed countries show up in the lesser weight and length increases in both fetal and early infancy growth. Similarly, excessive gestational weight gain is associated with increased risk of childhood overweight/obesity.

## NUTRITION

Nutrition is a major determinant of growth, especially during early childhood and adolescence. Worldwide, undernutrition is the single most important cause of growth retardation. Nutritional status also modulates the pubertal growth spurt and timing of adolescent sexual development. While undernutrition is usually associated with later age of menarche, moderate obesity may result in early sexual maturation. Voluntary undernutrition usually seen in adolescent girls, gymnasts and dancers impairs growth before epiphyseal fusion and delays puberty.

A well-balanced, age-appropriate diet that includes carbohydrates, protein, fats, vitamins, and minerals is necessary for optimal growth. The effects of nutrition and especially the effects of specific nutrients are often difficult to isolate as growth is affected by a multitude of factors. Deficiency of essential amino acids results in stunted growth. Zinc is a constituent of certain enzymes and is involved in protein synthesis; a deficiency of zinc causes stunting and interferes with sexual development. Iodine is essential for

synthesis of thyroid hormones. Iron deficiency anemia is known to affect linear growth. Vitamin A is needed for adequate osteoblastic activity and vitamin C for adequate formation of intercellular substance of bone. Similarly, calcium, phosphorus and other inorganic constituents such as magnesium and manganese are required for bone growth. Vitamin D deficiency causes rickets and retardation of linear growth.

The roles of specific nutrients like carbohydrates, protein, zinc, iron, copper, iodine and vitamin A, in the general linear growth faltering that occurs in developing countries are debated due to lack of adequate data. Interventions with each specific nutrient have been shown to have a positive effect on length gain in few studies, only weight gain in others or no effect in some studies. Also community-based interventions with supplementary feeding for promoting physical growth of children have produced conflicting results. Infant feeding practices have an influence on growth during first year of life with the breastfed infants generally remaining 0.5–0.6 kg lighter than formula fed infants.

The impaired growth in malnutrition especially in marasmus is associated with low GH and IGF-1 concentrations. However, GH levels are often elevated particularly in nonmarasmic malnutrition indicating a state of GH insensitivity. The elevation of GH is an adaptive mechanism to spare protein by lipolytic and anti-insulin actions of GH. The low IGF-1 probably shifts precious calories from growth to survival needs of the child. The accelerated linear growth after treatment of nutritional vitamin D deficiency is probably mediated through activation of the GH-IGF1 axis.

## HORMONES

A normal hormonal milieu is essential for growth during childhood and puberty. In fact, dysfunction of any hormonal system may affect growth. Major hormonal factors that affect growth are GH, IGF, testosterone, estrogen, thyroid hormones, cortisol and insulin.

### Growth Hormone

This is the most important hormone controlling growth from birth up to adolescence. GH promotes protein synthesis, inhibits the formation of fat and carbohydrate and is required for the proliferation of cartilage cells at the epiphyseal plate. Its synthesis and release from anterior pituitary are promoted by GH-releasing hormone (GHRH) and ghrelin, and inhibited by somatostatin. Thyroid and gonadal hormones particularly estradiol and testosterone and deep sleep increase pulsatile GH secretion and release whereas adiposity has a negative effect on GH production. Glucocorticoids, previously thought to have a negative influence on GH production, are now believed to play a positive role in maturation of functional somatotrophs.

Growth hormone stimulates growth through synthesis and release of IGF-1 in liver as well as through its direct effects on target tissues. In addition, it also stimulates production of acid-labile subunit and IGF-binding protein 3 (IGFBP3) in liver; proteins that are involved in the control of IGF-1 delivery to target tissues. GH related longitudinal growth is facilitated by stimulation of chondrocyte activity at the growth plate. This GH mediated chondroplasia and osteogenesis involve expression of new genes like IGF-1, IGF-1R and estrogen receptor and results in bone elongation that contributes about 60% to the total bone growth. GH also contributes to growth of other organs such as kidneys, adrenal glands and heart.

Factors that affect GH production or action at the tissue level affect growth. General factors like stress, exercise, malnutrition, and anorexia alter GH secretion and release. Changes in concentrations of various hormones that affect the GH-IGF1 axis as mentioned earlier may also result in growth retardation.

Growth hormone deficiency may result from disruption of GH axis in the higher brain, hypothalamus or pituitary by congenital or acquired conditions. Developmental anomalies of hypothalamus-pituitary area, mutations in *GHRHR* and *GH* genes, developmental defects of sella turcica and congenital absence or hypoplasia of pituitary gland are some of the congenital conditions that may result in GH deficiency either isolated or combined with other hormone deficiencies. Acquired or secondary GH deficiency may result from trauma, inflammation, tumors or irradiation involving brain and/or hypothalamus or pituitary.

Resistance to GH action either congenital as seen in Laron dwarfism or acquired as seen in malnutrition, hepatic or renal disease, and poorly controlled diabetes may result in growth faltering. GH resistance may also develop during GH therapy due to formation of GH inhibiting antibodies in patients harboring *GHI* mutations.

### Thyroxine

Thyroid hormones are essential for normal skeletal development; the growth plate being exquisitely sensitive to triiodothyronine (T3). The molecular mechanisms of thyroid hormone action within the developing bone are incompletely understood. Thyroid hormones act via two receptors, TR $\alpha$  and TR $\beta$  which are expressed by chondrocytes of the reserve, proliferative and pre-hypertrophic zones as well as by osteoblasts of the primary spongiosum but not by differentiated chondrocytes. It appears that T3 is essential for stimulating resting zone cells to differentiate to proliferating chondrocytes, for chondrocyte hypertrophy and differentiation, and for vascular invasion or angiogenesis of the growth plate.

In hypothyroid states, the growth plate is separated from the primary spongiosum by a mineralized interface that seals it off from vascular invasion and prevents further bone lengthening ultimately leading to growth retardation. Also, there is disruption of the normal functional continuity between maturing chondrocytes and mineralizing osteoblasts with markedly reduced osteoblast invasion and fewer, thinner bone trabeculae. Additionally, T3 influences expression of several components of GH-IGF-1 signaling in bone and also helps maintaining circulating concentrations of glucocorticoids (essential for maturation of somatotrophs) by regulating hepatic 11 $\beta$ -hydroxysteroid dehydrogenase.

### Sex Steroids

These are secreted by adrenals and gonads and interact with GH and IGF-1 during puberty to determine the pubertal growth spurt. Both GH and sex steroid hormones must be present for normal pubertal growth to occur. The role of sex steroids in promoting growth is limited in absence of GH and IGF-1 although they are known to have direct effect on growth. In patients with GH deficiency, GH replacement produces minimal pubertal spurt unless accompanied by sex steroid replacement. In conditions of sex steroid deficiency, the pubertal growth spurt is limited although prepubertal growth is unaffected. Both testosterone and estrogen modulate GH secretion by increasing the amplitude of GH pulses. Gonadal steroids also enhance bone mineral accrual and affect adult height by promoting epiphyseal fusion through direct effects on the growth plate. The sex steroid related growth is mainly mediated through estrogens rather than androgens. Children with complete androgen insensitivity have normal adolescent growth and achieve pubertal levels of GH and IGF-1 if sufficient concentrations of estrogen are present. Boys with inactivating mutations of estrogen receptor or aromatase gene show delayed skeletal maturation despite high levels of testosterone and continue to grow well into adulthood.

Gonadotropins secreted by anterior pituitary enhance skeletal maturation through growth of ovaries and testis which then secrete increased amounts of estrogen and testosterone. In cases of precocious puberty, the increase in sex steroids increase the immediate growth rate and the total pubertal height gain but the faster skeletal maturation decreases the period of prepubertal growth leading to loss of final height.

### Glucocorticoids

Adequate glucocorticoid production by adrenal glands is necessary for normal function of the somatotrophic axis as these help in maturation of somatotrops. In addition, glucocorticoids appear to regulate skeletal bone accumulation. However, glucocorticoid excess, especially if chronic, suppresses the secretion of GH and inhibits growth. Children with Cushing syndrome have short stature, excess adiposity and lower bone mineral density. Also chronic glucocorticoid administration in several common inflammatory conditions in children is known to be associated with linear growth failure.

### Insulin

Insulin plays an important role in the regulation of growth; its peripheral action may promote weight gain by facilitating storage of metabolic fuels and increased appetite while central action on appetite regulation appears anorectic. Insulin also interacts with other growth factors to influence fetal growth. Fetal macrosomia is common in diabetic pregnancies and correlates with fetal hyperinsulinemia. Weight gain is also noted in patients on insulin treatment. In children, however, the effect of insulin on body weight has remained a controversial topic. Growth studies in children with type 1 diabetes while exploring the relationship between insulin induced changes in weight and body composition have shown inconsistent results. Also, no effect of 2 years of insulin supplementation on body weight or physical development was seen in normal children in the diabetes prevention trial-type 1.

### Leptin and Ghrelin

Leptin produced in the adipose tissue sends satiety signals to brain thereby suppressing appetite and ghrelin, produced in the stomach provides hunger signals to the brain. Both these hormones may influence growth particularly during infancy. Plasma leptin concentrations have a positive relation to bodyweight while ghrelin is negatively associated with bodyweight in infants. The long-term effects of alterations in concentrations of leptin and ghrelin on bodyweight and composition are however unknown at present. *Leptin deficiency*, usually congenital, causes severe obesity in children. Relative leptin deficiency associated with shorter duration of sleep causes overweight or obesity in adults. Decreased ghrelin synthesis in children suffering from iron deficiency anemia affects their growth by reduction in appetite. The elevation of ghrelin concentrations in children with protein energy malnutrition occurs as an adaptation mechanism and may have a role in catch-up growth.

### Parathyroid Hormone and Vitamin D

They mediate bone growth probably through regulation of osteoblast proliferation and differentiation. Growth failure is a common manifestation of problems of parathyroid hormone (PTH) deficiency or action at the tissue level. Adequate levels of vitamin D are required for efficient calcium absorption to maintain blood levels of calcium and phosphorus essential for normal bone mineralization. Children with vitamin D deficiency develop rickets and short stature. Also vitamin D resistant states due to mutations of vitamin D receptor genes result in similar growth failure.

## MINOR GROWTH FACTORS

Numerous peptides and their receptors identified recently are proposed to play a role in somatic growth. The most notable are fibroblast growth factors and their receptors considered essential for normal bone growth. Mutations in *FGFR3* and *FGFR2* gene cause achondroplasia and craniosynostosis respectively. Epidermal growth factors may be involved in fetal growth. Certain peptides like hepatocyte growth factor, endothelin, nerve growth factor, etc., may have a role in promoting growth of specific tissues.

## PHYSICAL ACTIVITY

Physical activity and general fitness affects linear growth. Moderate physical activity is associated with cardiovascular benefits, favorable changes in body composition and bone mass accrual but excessive physical activity has a negative effect on growth and pubertal development. Wrestlers, gymnasts and dancers show decreased linear growth during the periods of intense training and catch-up growth afterwards. Physical exercise is associated with an increase in circulating levels of GH and IGF-1 as well as alterations in levels of several other hormones associated with appetite control.

## SYSTEMIC DISEASES

Growth failure is one of the usual manifestations of chronic systemic diseases. Infectious illnesses like recurrent diarrhea, human immunodeficiency virus (HIV) and tuberculosis account for majority of the cases of growth failure due to systemic diseases in many countries. Disturbances of GH-IGF-1 axis are presumed to be partly responsible for growth failure in HIV. Congenital heart disease can cause growth failure in affected infants and children due to excessive energy expenditures and chronic hypoxemia. Chronic renal disease especially renal tubular acidosis (RTA) and chronic renal failure (CRF) also cause growth faltering. Multiple mechanisms like reduced caloric intake, protein wasting, loss of electrolytes necessary for growth, reduced synthesis of activated vitamin D, insulin resistance, anemia and decreased cardiac functions combine to result in growth retardation in renal disease. Additionally, chronic systemic acidosis impairs growth partly through disturbances of GH-IGF-1 axis and patients with CRF may show GH resistance and decreases in IGF bioactivity due to impaired clearance of IGF-BPs. Gastrointestinal diseases like celiac disease, inflammatory bowel disease and cystic fibrosis affect growth by impairing intake or absorption of nutrients. Hematological disorders like thalassemia, sickle cell disease and leukemia cause growth failure probably through chronic anemia-related impaired oxygen delivery to tissues, increased cardiac workload, increased energy demands of hematopoiesis and impaired nutrition. Multiple hormone deficiencies (thyroid, IGF-1, gonadal steroids etc.) in thalassemia resulting from transfusion related iron overload also contribute to growth failure. Patients with diabetes mellitus especially those with a poor control also manifest growth failure probably due to caloric wasting, chronic acidosis, increased glucocorticoid production and associated hypothyroidism. Chronic hypoinsulinemia inhibits IGF-1 action by elevating IGF-BP1 concentrations as well as reducing IGF-1 levels by altering *GHR* expression. Severe growth retardation is however unusual in diabetes and modern management of diabetes is demonstrated to be associated with normal physical growth. Many inborn errors of metabolism like glycogen storage disorders, mucopolysaccharidoses and mucopolipidoses are associated with growth failure. Chronic pulmonary diseases especially cystic fibrosis (CF) and bronchial asthma affect growth through combined effects of pulmonary and pancreatic dysfunction in CF.

and effect of chronic steroid administration in asthma. In India, chronic worm infestations also cause growth failure by nutritional debilitation in many children.

### IN A NUTSHELL

1. Knowledge of factors that influence physical growth helps pediatricians to timely diagnose and treat conditions associated with growth deviation.
2. Normal growth represents constant interaction of genetic, hormonal, nutritional and several other environmental factors.
3. Nutrition is the single most important factor affecting body growth during early childhood and adolescence.
4. Normal functioning endocrine system, in particular the pituitary-thyroid unit, is essential for normal physical growth.

## Chapter 19.3

# Assessment of Physical Growth

Anju Seth, Rajni Sharma

Growth is an integral aspect of childhood and being able to accurately measure, record and interpret a child's growth parameters is an essential clinical skill for pediatricians. The most important parameters for assessing physical growth include weight, length/height and head circumference. Other parameters such as mid-arm circumference, waist circumference and skinfold thickness are measured when indicated. There are certain prerequisites to ensure accurate measurement. First, the instruments used for measurement should be well maintained and functioning appropriately. It is important to calibrate the instruments at regular intervals especially weighing scales against standard weights. The person taking the measurements should be well-trained and should follow a standardized technique of taking measurements.

## TECHNIQUES OF GROWTH MEASUREMENT

### Weight

Weight is measured by a spring balance, beam balance or a digital scale. The spring balance tends to give inaccurate readings due to change in the elasticity of the spring over time and is therefore not the preferred device. Irrespective of type of weighing scale used, always check for and correct zero error. Infants should ideally be weighed nude on an infant weighing scale. Ensure that the infant is centered on the measuring tray. Older children should be weighed wearing minimum clothing after removing footwear. If the child cannot be weighed individually, she/he can be placed in the parent's arms and the parent's weight can later be deducted from the combined weight to get the child's weight. Many electronic weighing machines have the provision of taking *tare weight*. In commercial language, *tare weight* refers to the weight of the container/packaging. In practice, when the caregiver stands on the scale, the *tare weight* button is pressed which resets the weight to zero. Subsequently, the child can be placed in the caregiver's arms while the latter is still standing on the scale and the child's weight can be directly read. The weighing scale used for infants should be able to measure weight to the nearest 10 g, while the scale for older children should measure to the nearest 100 g.

### Length/Height

Recumbent length is measured for children less than 2 years of age by an *infantometer*. This consists of a fixed headboard with a moveable foot-board. Two persons are required to take an accurate measurement. The first person holds the infant's head against the headboard with the eyes looking straight up (the Frankfurt plane, an imaginary line from the center of the external auditory meatus to the lower border of the eye socket, should be vertical) while the second person keeps the knees straight by pressing them down gently and moves the footboard up till the soles are resting flat on it and the toes are pointing upwards (**Figs 1A to C**). If a child is less than 2 years old and does not lie down for measurement, one can measure standing height and add 0.7 cm to convert it to length.

After the age of 2 years, standing height should be measured by the *stadiometer*. This consists of a vertical ruler and horizontal sliding headpiece which rests on the top of the head. The child should stand without shoes and socks with the heels, buttocks and shoulder blades touching the wall and the Frankfurt plane parallel to the ground. The measurer applies slight pressure on the mastoid processes to make the child stand erect (**Figs 2A and B**). A simple

stature-meter that can be fixed to the wall manually and pulled down to measure height is a satisfactory alternative in clinical practice (**Figs 3A and B**). If a child aged 2 years or older cannot stand, one can measure recumbent length and subtract 0.7 cm to convert it to height.

### Head Circumference

Head circumference is routinely measured in infants and children up to 3 years of age. All newborn babies should have their head circumference measured but not before 36 hours of age (due to the presence of caput). The tape should pass around the occipital prominence at the back and over the supraorbital ridges just above the eyebrows so that the maximal circumference is measured. One should use a flexible nonstretchable tape and measure to the nearest 0.1 cm (**Fig. 4**).

### Other Measurements

#### Mid-upper Arm Circumference

The measurement of mid-upper arm circumference (MUAC) is useful to assess the nutritional status of children between 6 months and 5 years of age. It can be used as an age-independent criterion to identify malnutrition and is especially useful in the community setting when weight and stature cannot be measured or the child's exact age is not known. MUAC is measured in the left arm after locating the mid-point (between the tip of the left shoulder, i.e., acromion process and tip of the elbow, i.e., olecranon process). The arm should be hanging loosely at the side while measuring MUAC. One should take care that the tape is neither too tight nor too loose when encircling the arm (**Fig. 5**).

#### Waist Circumference

Central or truncal obesity is considered a risk factor for developing cardiovascular disease and diabetes (metabolic syndrome). Waist circumference is an easy and validated measure of central obesity. It is measured midway between iliac crest and lowermost margin of the ribs. While absolute cut-off levels of waist circumference are available for screening for obesity related complications in adults, age and gender related waist circumference percentiles should be used in children. Ideally, ethnic specific charts should be used.

#### Skinfold Thickness

Skinfold thickness helps to assess the degree of fat deposits or adiposity at particular body sites including triceps, chest, abdomen, suprailiac region and thigh. A pinch of skin is taken between the thumb and forefinger above the muscle plane and calipers are applied for reading. The values can be compared to reference data or can be used in standardized equations to calculate total fat mass or percentage of body fat. Agarwal KN et al. (2001) have published Indian reference data for skinfold thickness in children. Skinfold thickness has limited application in routine clinical practice, being used mostly as a research tool.

### Common Errors in Recording and Interpreting

#### Anthropometric Parameters

Familiarity with the technique of measurement and the instrument is essential for accurate measurements; lack of training and experience can lead to errors. Errors can arise if one attempts to take length in infants without using the infantometer or if a single person attempts to use the infantometer (at least two persons are required). For height, it is important to ensure that the head end of the instrument is not floppy. If using a stature-meter, it is critical to affix it to a smooth wall or another suitable surface at the exact height specified by the manufacturer. All headgear, hair accessories, thick socks and shoes should be removed while measuring height. Care must be taken that proper position is maintained and the child

**Figures 1A to C** Technique of recording length of a child using an infantometer

does not stand on his/her heels. Weight may vary with the time of day, feeding and excessive clothing as in winters. While measuring head circumference, errors may arise if a stretchable tape is used or if the tape slips off the head while measuring.

Errors can also arise while interpreting the measured parameters, the most common error being erroneous determination of child's age, use of inappropriate growth reference table/chart (described later) and in selecting the correct line on the growth reference table for comparison. It is advisable to familiarize

**Figures 2A and B** (A) Technique of recording height using a stadiometer; (B) Measuring tape with sliding head-board

oneself with one particular set of reference tables/graphs and use the same consistently in clinical practice. This would provide a uniform reference over time and minimize errors as well.

### Recommendations for Intervals and Parameters for Growth Monitoring

Weight, length and head circumference should be measured at birth and subsequently at immunization contacts at 6 weeks, 10 weeks and 14 weeks, 9 months, 15 months and 18 months. Between the ages of 18 months and 5 years, weight and height should be monitored 6 monthly. Beyond 5 years, as the rate of growth becomes slower, annual assessment of height, weight and body mass index (BMI) will suffice. Growth can also conveniently be assessed as and when the child is brought to the physician for any other reason.

### GROWTH REFERENCE STANDARDS

Though growth is a complex process regulated by multiple factors such as genes, health, nutrition and socioeconomic factors, it follows a fairly predictable pattern. This has led to the concept of *growth reference standards* to depict expected patterns of growth. Growth standards are usually generated from cross-sectional data by single-time observations on a large population of children of various ages. They can also be derived from longitudinal data collected over a period of time from a large cohort. The data

**Figures 3A and B** (A) A stature-meter; (B) Height being recorded using a stature-meter by pulling down the headpiece of the meter fixed on the wall

**Figure 4** Technique of recording the head circumference

so generated is statistically computed and presented as tables. Growth charts are graphic representations of the data presented in growth tables and typically depict 3rd, 10th, 25th, 50th, 75th and 97th percentile lines. An individual child's growth parameters can be compared to these reference standards using the reference table

in office practice or, ideally by plotting on a growth chart where a longitudinal record of an individual child's growth can be kept. Various types of growth tables/charts are available separately for both genders, including weight-for-age, height-for-age, weight-for-height, head circumference-for-age and BMI-for-age.

### Growth Charts

The first Indian growth charts available for clinical use were derived from the Indian Council of Medical Research (ICMR) Technical Report Series no. 18 (1972), which were developed more than four decades ago and were based on studies on children from mixed socioeconomic strata. Despite being criticized for the method of sample selection and data collection, they remained in use for many years for growth monitoring in India.

Common growth reference data being used in clinical practice are compared in **Table 1** and discussed here.

### World Health Organization (WHO) Charts

World Health Organization (WHO) growth standard tables and charts are available from birth to 19 years of age. The standards for preschool children (age 0–60 months) were developed from data collected in the WHO International Multicenter Growth Reference Study (MGRS) carried out from 1997 to 2003 in six centers worldwide—California (USA), Muscat (Oman), Oslo (Norway), Pelotas (Brazil), Accra (Ghana) and Delhi (India). The subjects of this study included healthy breastfed infants living in optimal socioeconomic conditions and thus the growth charts describe how children should grow in all settings rather than describing how they grow in a specific setting and time. This study combined longitudinal follow-up as well as cross-sectional data of children and provides the best physiological growth standards from birth to 5 years of age in breastfed infants. These standards are used to assess growth of children in all parts of the world irrespective of ethnicity. When using the WHO growth standard, fewer children aged 0–60 months are diagnosed with poor weight gain, compared with the US Centers for Disease Control and Prevention (CDC) growth reference.

**Figure 5** Technique of recording mid-upper arm circumference (MUAC)

The WHO reference curves for ages 5–19 years, were developed from the original 1977 National Center for Health Statistics (NCHS) data (given later) based on anthropometric data of American children. To develop reference curves for this age group, WHO used the original nonobese sample from NCHS data supplemented with

**Table 1** Growth charts available for clinical use

Country	USA	Multicountry/USA	India		
Growth Chart	CDC 2000	WHO	Agarwal KN et al.	Khadilkar VV et al.	Marwaha RK et al.
Year	1964–1994	1997–2003	1988–1991	2007–2008	2006–2009
Data	Weight data from original NCHS 1977	Primary data for 0–5 years, reconstructed NCHS data for > 5 years	Primary data	Primary data	Primary data
Population	USA, nationwide data, mixed feeding	Six countries pooled data, healthy breastfed children	Affluent Indian population, mixed infant feeding, multicentric	Affluent Indian population, multicentric	Affluent Indian population, multicentric

data from the WHO MGRS study to facilitate smooth transition at 5 years. This was achieved by applying state-of-the-art statistical methods. The full set of WHO reference tables and charts are freely available on the WHO website ([www.who.int/childgrowth/en](http://www.who.int/childgrowth/en)).

### Centers for Disease Control and Prevention (CDC) Charts

The CDC 2000 growth charts are revised versions of NCHS 1977 growth charts, which were based on cross-sectional data collected in the USA from nation-wide studies. The CDC charts comprised of revision of previous existing 14 charts using improved statistical tools, and introduction of two new BMI charts. The CDC 2000 charts are based on data from five nationally representative surveys conducted at various times and places between 1963 and 1994 with supplementary data for birthweight and for infants under 2–3 months of age from other sources since no national data was available.

The sample population was ethnically heterogeneous and infants were predominantly on formula/mixed feeding as breastfeeding was not the norm at the time data was collected. Hence, CDC 2000 may not truly reflect the ideal growth of breastfed babies. The full set of charts is freely available at [www.cdc.gov/growthcharts](http://www.cdc.gov/growthcharts).

### Indian Reference Charts

In 1992, Agarwal DK et al. published growth reference data from a major multicenter study from India which were subsequently used to develop growth charts. In this study, height and weight were recorded cross-sectionally from 1988 to 1991 in affluent Indian children aged 0–18 years and percentile charts were generated for the same. The data for birth to 6 years was collected from six cities over 1985–1987 using a mixed longitudinal study design (1994). Data for the age group 5–18 years was collected from nine Indian states over 1988–1991 using a cross-sectional study design (1992 and 2001).

Apart from the growth reference data by Agarwal KN et al., several recent multicentric studies including those by Khadilkar VV et al. (2009 and 2010) and Marwaha RK et al. (2011) have generated more recent reference data on height, weight and BMI in Indian children. A comparison of growth reference data from these studies is shown in **Figures 6A and B**.

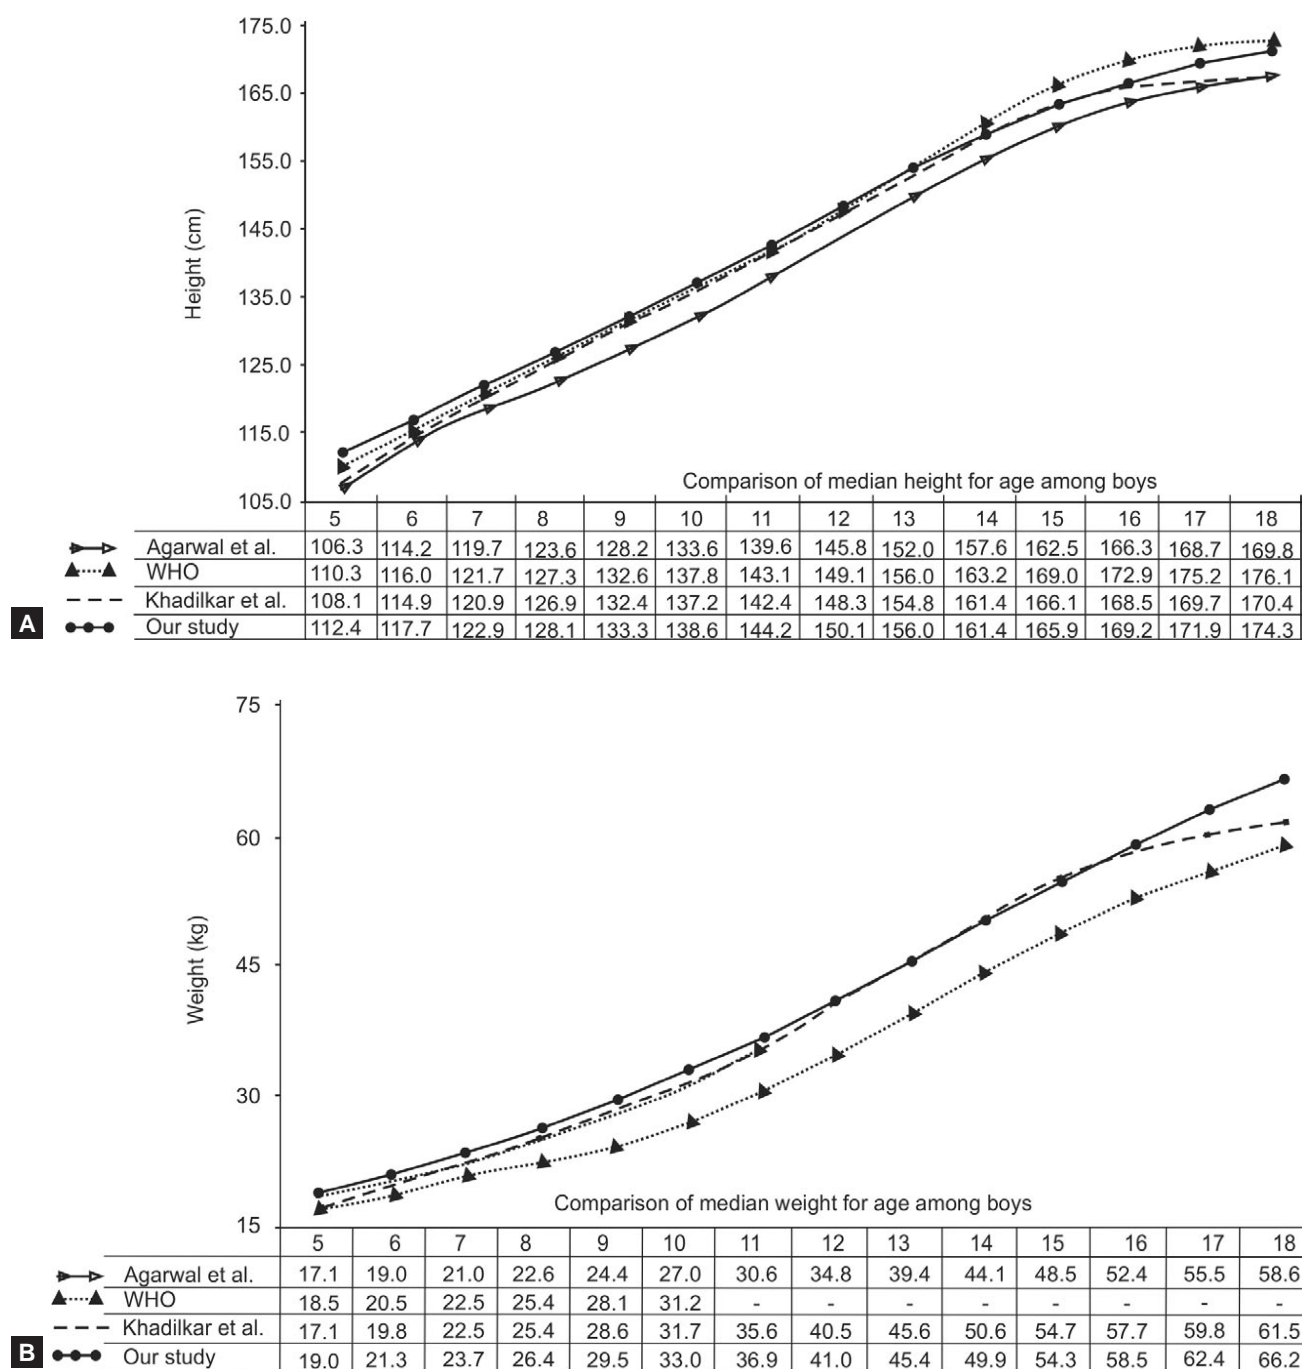

Since their introduction, WHO 2006 standards have been widely accepted world-over for monitoring growth of under-five children. The Government of India has endorsed these standards for under-five growth monitoring. The United Kingdom and the United States of America have adopted the WHO 2006 standards till the age of 4 and 2 years, respectively for growth monitoring followed by charts based on local references. It is important to realize that while interpretation of growth in a child may vary depending on the reference standards used for comparison, and will therefore have implications at community/national level, choice of a specific growth reference chart may not be critical for growth monitoring of a particular child in clinical practice. It is more important to be accurate in assessment and plotting and to be consistent with the type of reference used for that individual.

WHO growth reference data tables and charts are presented in **Tables 2 to 10 and Figures 7 to 12**. After the age of 5 years, nationally representative references for height and weight should be used. Growth reference data by Agarwal DK et al., and growth charts based on them are included in **Tables 11 to 16 and Figures 13 and 14**.

## INTERPRETATION OF ANTHROPOMETRIC PARAMETERS

### Concept of Z-Score, Percentiles, and Percentage of Median

Growth parameters of an individual needs to be compared with the reference data to interpret them. This can be done in various ways. *Percentiles* are obtained by dividing an ordered set of data into 100 equal sized groups. An observed measurement at the 50th percentile indicates the median value and that half of the population has values above and other half has values below the median. If an individual's height is at 3rd percentile value, it means that 3% of all individuals in the population have height less or equal to that value and 97% of the population has height above that value. The 3rd and 97th percentile, which roughly correspond to  $\pm 2$  standard deviation (SD) and include 95% of all observations, are conventionally considered as limits of normalcy for height and weight.

**Figures 6A and B** Median height and weight of Indian boys as per data from study by Marwaha RK et al. in comparison to World Health Organization (WHO) data and other Indian studies

Source: Marwaha RK, Tandon N, Ganie MA, et al. Nationwide reference data for height, weight and body mass index of Indian school children. Natl Med J India. 2011;24:269-77; Reproduced with permission.

*Standard deviation score (SDS) or Z-score* refers to the number of standard deviations an individual measurement is away from the median. A positive (+) SDS denotes a value above the median and negative (-) SDS denotes a value below the median. Measurements that lie between +2 and -2 SDS of the median value are considered to be normal whereas, measurements that have an SDS more than +2 or less than -2 are considered to lie outside the range considered normal for a given population. In a normally distributed population, approximately 95% of individuals have values between -2 and +2 SDS. A Z-score of -2 corresponds to the 2.5th percentile and Z-score of +2 to the 97.5th percentile. Individuals with their

parameters lying outside this range thus constitute 5% of all subjects of that gender and age and should therefore be carefully evaluated for any disorder of growth. For normally distributed (parametric) data, like height, the following formula can be used for calculating SDS or Z-score of a given observation:

$$\text{SDS (Z-score)} = \frac{(\text{observed value} - \text{median value of the reference population})}{\text{Standard deviation value of reference population}}$$

For nonparametric data like weight, more complicated formulae are required to calculate the SD score of a given observation

**Figure 13** Growth chart for Indian boys aged 5–18 years

Source: Based on Agarwal DK, Agarwal KN, Upadhyay SK, et al. Physical and sexual growth pattern of affluent Indian children from 5 to 18 years of age. *Indian Pediatr.* 1992;29:1203-82.

and various computerized programs are available for this purpose. WHO gives a freely downloadable anthropometric calculator at its website for calculation of Z-scores based on WHO reference ([www.who.int/childgrowth/software/en/](http://www.who.int/childgrowth/software/en/)).

Another way to compare anthropometric measurements of a child with reference data would be as a *percentage of the median value*. For height, a value less than 90% of the median value is considered as short stature and for weight values less than 80% are considered as underweight. These percentage cut-offs roughly correspond to  $-2$  SDS. Both SDS and percentage of median can be used for generating summary statistics like mean and standard deviations in population based studies, and thus have an advantage over using percentile based comparison.

## Interpretation of Growth Parameters

### Weight for Age

Weight for age is a measure of weight of a child compared to the weight of children of the same age and gender from a reference population. A child whose weight for age is below  $-2$  Z-score is underweight and below  $-3$  Z-score is severely underweight.

**Figure 14** Growth chart for Indian girls aged 5–17 years

Source: Based on Agarwal DK, Agarwal KN, Upadhyay SK, et al. Physical and sexual growth pattern of affluent Indian children from 5 to 18 years of age. *Indian Pediatr.* 1992;29:1203-82.

### Weight for Length/Height

Weight for length/height is a measure of weight compared to the weight of children of the same gender and length/height from a reference population. It is an indicator of acute malnutrition independent of age. A child whose weight for length/height is below  $-2$  Z-score is wasted and below  $-3$  Z-score is severely wasted. WHO and CDC weight for length/height standards are available for children.

### Height/Length for Age

Height/length for age is a measure of length/height compared to the length/height of children of the same age and gender from a reference population. It is an indicator of chronic malnutrition/short stature. A child whose length/height for age is below  $-2$  Z-score is stunted and below  $-3$  Z-score is severely stunted. A height of less than  $-2$  SDS is also the conventionally accepted definition of short stature.

### Body Mass Index

Body mass index (BMI) is used to assess the nutritional status of children more than 5 years of age instead of weight for length.

**Table 11** Height percentiles of Indian boys 5–18 years age

Source: Agarwal DK, Agarwal KN, Upadhyay SK, et al. Physical and sexual growth pattern of affluent Indian children from 5 to 18 years of age. *Indian Pediatr.* 1992;29:1203-82; Reproduced with permission.

BMI is kilograms (kg) of body weight per height in meters squared ( $\text{m}^2$ ), i.e.  $[\text{BMI} = \text{weight in kg}/(\text{height in m})^2]$ . A BMI of  $18.5\text{--}24.99 \text{ kg/m}^2$ , is considered normal for adults. Adults are defined as underweight if their BMI is  $< 18.5 \text{ kg/m}^2$ , overweight if it is between  $25 \text{ kg/m}^2$  and  $29.9 \text{ kg/m}^2$  and obese if more than or equal to  $30 \text{ kg/m}^2$ . For children, there is no absolute BMI cut-off as BMI values change with age. Age and gender-specific BMI percentile curves are available in all reference data sets in common clinical use. Children with BMI less than 5th percentile are classified as underweight. The definitions of childhood overweight and obesity are BMI above or equal to the 85th and 95th percentile, respectively. In the recent Indian reference charts (Marwaha RK et al. 2011, Khadilkar VV et al. 2009), the 85th and 95th percentile for BMI at age 18 years in boys exceeded the adult BMI cut-off values for overweight and obesity of 25 and 30 respectively. As proposed by International Obesity Task Force (IOTF), Khadilkar VV et al. have published cross-sectional age and gender-specific BMI cut-offs for Indian

children linked to proposed Asian adult cut-offs of 23 and  $28 \text{ kg/m}^2$  for the assessment of risk of overweight and obesity (2012). These lower BMI cut-offs of 23 and  $28 \text{ kg/m}^2$  have been suggested for overweight and obesity, respectively for Asian adults, as they are more prone to adiposity and central obesity at a lower BMI than their western counterparts.

### Waist Circumference

Specific ethnic cut-off levels of waist circumference are available for screening for obesity related complications. These correspond to values greater than 80–88 cm, in Indian women and men, respectively. Waist circumference reference charts for Indian children (Khadilkar VV et al., 2014—multicentric data from five cities in different zones of India; and Kuriyan R et al., 2011—from Bengaluru) are available. The authors have recommended a cut-off value more than or equal to 70th percentile and more than or equal to 75th centile, respectively, for diagnosing obesity and screening for metabolic syndrome (Tables 17 and 18).

## GROWTH MONITORING: LONGITUDINAL ASSESSMENT OF GROWTH

One-time assessment of growth parameters gives information on how the child is at that particular time, without any relation to what he/she has been like in past. It thus has limited scope for interpretation. Growth is best evaluated longitudinally by measuring and recording on a growth chart, serial recordings of anthropometric parameters. Growth monitoring consists of regularly measuring anthropometric parameters (weight and length/height) in a child and recording them on a growth chart. An accurately maintained growth record is a very sensitive indicator of growth abnormalities. It helps in diagnosing ill health or nutritional imbalance, as well as monitoring response to remedial interventions. Growth monitoring is a potent tool used in primary health-care for identifying malnourished children and their response to nutritional interventions. In case of well babies, growth monitoring may help to reassure and educate the mother about feeding practices.

The growth curve of most normal children would fall between 3rd and 97th centile lines and would be parallel to these lines. The particular centile line followed by the child is determined by his/her genetic potential. This is determined by the *mid-parental height* (MPH). MPH is the average of the parents height and is calculated by the following formula

$$\text{MPH for boys (in cm)} = \frac{\text{Father's height} + \text{Mother's height} + 13}{2}$$

$$\text{MPH for girls (in cm)} = \frac{\text{Father's height} + \text{Mother's height} - 13}{2}$$

The MPH is plotted on the child's growth chart at 18 years of age. If the child's growth curve is extrapolated to 18 years of age, it should ideally lie  $\pm 2\text{SD}$  of the MPH (this is approximately  $\pm 8\text{ cm}$ ). **Figure 15** shows a child growing normally parallel to the centile lines with the extrapolated height at 18 years within the limits of his MPH. A child whose growth is clearly out of the MPH range, even though it might still be within 3rd and 97th centiles, needs careful evaluation. Also, since children

Weight-for-age and Height-for-percentiles Boys (5–18 years)

Name-----Date of birth-----Record No-----

**Figure 15** Growth chart of an 11.5-year-old boy showing height growth parallel to and in between the 3rd and 25th centile lines and weight along the 50th centile. Mid-parental height (MPH) and target range for height is shown at 18 years of age. When the boy's growth curve is extrapolated to 18 years, the height is within  $\pm 8$  cm (target range) of the MPH

normally grow parallel to their respective centile lines, crossing over of two major centile lines, especially between the age of 2 years and the onset of puberty, i.e. roughly 10 years of age, is considered abnormal and may point to a pathological diagnosis or nutritional problems.

### IN A NUTSHELL

1. It is recommended that the World Health Organization (WHO) growth charts (0–60 months), which are based on growth of exclusively breastfed babies and depict the best physiological growth standards from birth to 5 years of age, be used to record and monitor growth in young children. Use of local reference charts is preferred for children beyond 5 years.
2. Anthropometric measurements from an individual child can be compared with standard reference growth charts or tables with the help of percentile values, standard deviation scores or percentage of the median.
3. Growth monitoring, that comprises of regularly measuring anthropometric parameters (weight and length/height) in a child and recording them on a growth chart, is a potent tool for diagnosing growth faltering and nutritional problems as well as monitoring response to therapeutic interventions.

Recently, Indian Academy of Pediatrics has developed new growth reference data and charts for Indian children more than five years of age while endorsing use of WHO growth charts for younger children. The new data set had been developed by collating data from multiple studies from different parts of the country. New IAP guidelines incorporating this information were published in January 2015, while this book was in press, these can be accessed from the website of IAP.

## Chapter 19.4

### Dental Development and Anomalies

Sunanda Roychoudhury, Shakil Ahmed Nagori,  
Ajoy Roychoudhury

#### DEVELOPMENT OF THE DENTITION

The development of the dentition includes the processes of tooth eruption and of the development of occlusion posteruption. Three distinct phases of tooth development can be recognized that ultimately lead to the establishment of the full dentition. First, there is a phase termed the *pre-eruptive phase*, which starts with the initiation of tooth development and ends with the completion of the crown. Second, there is the *phase of tooth eruption* (pre-functional phase), which begins once the roots commence to form. Third, after the teeth have emerged into the oral cavity, there is a protracted phase concerned with the development, and maintenance, of occlusion (the *functional phase*).

The human dentition is usually categorized as being primary, mixed (transitional), and permanent dentition. The transition from the primary/deciduous dentition to the permanent dentition is of particular interest because of changes that may herald the onset of malocclusion and provide for its interception and correction.

#### Pre-Dentition Period

This is from birth to 6 months. At this stage, the infant is edentulous. Both jaws undergo rapid growth; the growth is in three planes of space: (1) downward, (2) forward, and (3) laterally. Forward growth for the mandible is greater. Occasionally, there may be a neonatal tooth present at birth. It is a supernumerary tooth and is often lost soon after birth. At birth, one would often see bulges in the developing alveoli preceding eruption of the deciduous teeth.

#### Deciduous Dentition Period

The deciduous teeth start to erupt at the age of 6 months and the deciduous dentition is completed by the age of approximately 2½ years (**Figs 1 and 2**). The jaws continue to increase in size at all points until about 1 year. After this, growth of the arches is in the form of lengthening at their posterior (distal) ends. Also, there is slightly more forward growth of the mandible than the maxilla.

**Figure 1** Maxillary deciduous dentition

**Figure 2** Mandibular deciduous dentition

**Table 1** Development of deciduous dentition

Tooth	First evidence of calcification (months in utero)	Crown completed (months)	Eruption (months)	Root completed (years)
<i>Maxillary</i>				
Central incisor	3–4	4	7	1½–2
Lateral incisor	4½	5	8	1½–2
Canine	5	9	16–20	1½–3
First molar	5	6	12–16	2–2½
Second molar	6–7	10–12	21–30	3
<i>Mandibular</i>				
Central incisor	4½	4	6½	1½–2
Lateral incisor	4½	4	7	1½–2
Canine	5	9	16–20	1½–3
First molar	5	6	12–16	2–2½
Second molar	6	10–12	21–30	3

Many early developmental events take place in this period; the tooth buds anticipate the ultimate occlusal pattern. Mandibular teeth tend to erupt first. The pattern for the deciduous incisors is usually in this distinctive order: mandibular central; maxillary central incisors; and then all four lateral incisors. By 1 year, the deciduous molars begin to erupt. The eruption pattern for the deciduous dentition is described in **Table 1**. If deciduous teeth are retained too long, one must consider ankylosed teeth or missing or impacted teeth.

#### Occlusal Changes in the Deciduous Dentition

The term *occlusion* is used to describe the relationship of maxillary and mandibular teeth with each other. Broadly it is used to describe anterior relationship, i.e., the relationship of incisors and canines or posterior relation which is the relationship of molars. The incisor relationship in any dentition is usually described by the terms *overjet* and *overbite* (**Fig. 3**). Overjet is the anteroposterior overlap while overbite is the vertical overlap between incisor teeth. In the deciduous dentition, overjet and overbite are minimal and often decrease with age due to the gradual wear and tear of teeth. The molar relationship describes the relation of second deciduous molars with each other. In normal molar relation of deciduous dentition, the distal surfaces of maxillary and mandibular second deciduous molars are in one plane when both the teeth are occluded (**Figs 4A to C**). Other relations described are the mesial

**Figure 3** Vertical overlap between incisors is termed as overbite while horizontal overlap is termed as overjet

**Figures 4A to 4C** Occlusal relationship in deciduous dentition (D, distal surface; M, mesial surface). (A) Flush terminal plane; (B) Mesial step; (C) Distal step

step or distal step. In a mesial step molar relation, the distal surface of mandibular second deciduous molar is mesial to its maxillary counterpart. Such type of primary dentition predisposes to a “class III malocclusion” in the permanent dentition. The other type is the distal step molar relationship. In this case, the distal surface of mandibular second deciduous molar is distal to its maxillary counterpart. Such type of primary dentition predisposes to a “class II malocclusion” in the permanent dentition.

Spacing between teeth is a common feature of deciduous dentition (**Fig. 5**). This is because the permanent teeth which would be finally occupying the space in the arches are larger in size than primary teeth.

### Mixed Dentition Period

The mixed dentition period begins with the eruption of the first permanent molars distal to the second deciduous molars at around 6 years of age and ends when the last deciduous tooth is lost. It is an important phase in the life of the child as the deciduous dentition is completely replaced by the permanent dentition.

The deciduous incisors, canines and molars are replaced by the permanent incisors, canines and premolars respectively. The permanent molars do not replace any deciduous tooth and erupt distal to the deciduous dentition (**Fig. 6**). The first permanent molars initially articulate or occlude in an *end-on* relationship after eruption. In the mixed dentition, the deciduous second molars

**Figure 5** Primate spacing in deciduous dentition. (A) Maxillary primate space mesial to canine; (B) Mandibular primate space distal to canine

**Figure 6** Radiograph of a patient in mixed dentition stage. The permanent incisors and 1st molars have completely erupted. Canines and premolars are yet to erupt. 2nd and 3rd molars are seen developing distal to 1st molars

have a special importance for the integrity of the permanent dentition. Consider this: The first permanent molars at age 6 years erupt distal to the second deciduous molars. Permanent posterior teeth exhibit physiological mesial drift, i.e., the tendency of the tooth to drift mesially when space is available. If the deciduous second molars are lost prematurely, the first permanent molars drift anteriorly and block out the second premolars. This would hinder its eruption and result in an impacted second permanent premolar.

The deciduous anterior-incisors and canines are narrower than their permanent successors mesiodistally. The deciduous molars are wider than their permanent successors mesiodistally. This size difference has clinical significance. The difference is called the leeway space (**Fig. 7**).

Another feature which may be seen in a developing dentition is the flaring of permanent central incisors after eruption. This is called the “ugly duckling stage” (**Figs 8A and B**). This occurs due to late eruption of the permanent canines in the permanent dentition. While the central incisors erupt vertically the developing canine exerts pressure on the roots of the central and lateral incisors causing a typical flaring. This feature usually resolves when the canines have erupted into the arch.

### Permanent Dentition Period

The permanent dentition consisting of 32 teeth is completed from 18 years to 25 years of age if the third molars are included. The chronology of eruption of permanent teeth is given in **Table 2**. Maxillary/mandibular occlusal relationships are established when the last of the deciduous teeth are lost. The incisor relationship in a normal fully developed permanent dentition usually results

in a 2 mm overjet and overbite. A normal molar relationship is characterized by the occluding of mesiobuccal cusp of the first permanent maxillary molar in the mesiobuccal groove of the first permanent mandibular molar. This is known as the Angle's

**Figure 7** Illustration of leeway space in maxillary and mandibular arches

**Figures 8A and B** Ugly duckling stage. (A) Flaring of maxillary central incisors seen due to eruption of canines; (B) This stage resolves spontaneously with complete eruption of canines

**Figures 9A to C** Angle's molar relationship in permanent dentition. (A) Class I molar relationship; (B) Class II molar relationship; (C) Class III molar relationship

**Table 2** Development of permanent dentition

Tooth	First evidence of calcification	Crown completed (months)	Eruption (months)	Root completed (years)
<i>Maxillary</i>				
Central incisor	3–4 months	4–5	7–8	10
Lateral incisor	10–12 months	4–5	8–9	11
Canine	4–5 months	6–7	11–12	13–15
First premolar	1½–1¾ years	5–6	10–11	12–13
Second premolar	2–2½ years	6–7	10–12	12–14
First molar	Birth	2½–3	6–7	9–10
Second molar	2½–3 years	7–8	12–13	14–16
Third molar	7–9 years	12–16	17–21	18–25
<i>Mandibular</i>				
Central incisor	3–4 months	4–5	7–8	10
Lateral incisor	3–4 months	4–5	8–9	11
Canine	4–5 months	6–7	11–12	13–15
First premolar	1¾–3 years	5–6	10–11	12–13
Second premolar	1¼–2½ years	6–7	10–12	12–14
First molar	Birth	2½–3	6–7	9–10
Second molar	2½–3 years	7–8	12–13	14–16
Third molar	8–10 years	12–16	17–21	18–25

Class I molar relation. If the maxillary cusp occludes anterior to the mesiobuccal groove it results in a Class II molar relationship while if it occludes posterior to the mesiobuccal groove a Class III molar relationship is seen (**Figs 9A to C**). The maxillary teeth are also seen to be more buccal of the mandibular teeth. This maxillary overhang provides protection from check biting during mastication.

## OCCUSION AND MALOCCLUSION

Various changes occur during dental and facial development starting from birth to the age of 18 years. What may be normal at one stage of development can be abnormal at another stage. At birth there are no teeth present and the gum pads meet only in the posterior region. This anterior space between the gum pads facilitates the process of suckling where in the tongue positions itself. The mandible is small in comparison to the maxilla. The mandible at this stage thrusts forwards with every act of suckling. The first teeth erupt at the age of 6–7 months and the deciduous dentition is completely erupted by the age of 2 years. There are

various typical features of deciduous dentition, which are normal for that stage.

- Generalized space between teeth
- Primate or anthropoid spaces
- Deep bite/edge to edge bite of incisors
- Upright incisors
- Flush terminal plane of molars.

Once permanent teeth start to erupt at the age of 6 years the spacing between teeth gradually disappears as the larger anterior permanent teeth replace the smaller deciduous anterior teeth. By 12 years all the deciduous teeth are replaced by their permanent successors. At 12 years there are 28 teeth present, 14 in each jaw. The teeth of maxilla and mandible meet each other in a cusp-fossa relationship. *This is referred to as occlusion.* Normal occlusion is when the mesiobuccal cusp of the 1st maxillary permanent molar occludes with the mesial groove of the mandibular 1st permanent molar (Class I molar relation) and all the posterior teeth fit with each other with an overjet and overbite of 2 mm each in the anterior teeth (**Fig. 10**). *Any deviation from the normal occlusion is termed as malocclusion.* The malocclusion can have a dental origin/component or skeletal origin/component or both. Skeletal component is when there is discrepancy between the maxillary and mandibular skeletal size and position.

### Angle's Classification of Malocclusion

#### Angle's Class I Malocclusion

The molar relationship in permanent dentition occlusion is Class I but the rest of the teeth are not in normal alignment. There could

be crowding or spacing or rotation of individual teeth. There could also be anterior or posterior open bite or increased overjet or proclination of teeth. The face in Class I malocclusion is in balance and has pleasing esthetics. The facial profile is straight, the lips are competent and the musculature is relaxed. The maxilla and mandible are normal in size and position. This malocclusion is mainly dental in origin (**Figs 11A to D**).

#### Angle's Class II Malocclusion

The maxillary 1st permanent molar is more anterior to the mandibular 1st permanent molar. The distobuccal cusp of the maxillary molar occludes with the mesial groove of mandibular 1st molar. There is an increased overjet and deep over bite (**Figs 12A to D**). The maxilla and mandible are not in normal relation to each other. The maxilla may be prognathic or mandible may be retrognathic or there may be combination of both. The facial profile is convex. The midface is prominent, chin is retrusive. The lips may be incompetent. There is strain in musculature of face. The upper lip may be hypotonic, the lower lip may be thick, everted and redundant. There may be a lip trap present, where the lower lip rests behind the upper anterior teeth. The mentolabial sulcus is deep. In addition to dental malocclusion there is a skeletal component present in malocclusion. This type of malocclusion should be treated at an early age.

#### Angle's Class III Malocclusion

The maxillary 1st permanent molar is posterior to the mandibular 1st permanent molar. The mesiobuccal cusp of the maxillary 1st molar occludes with the distal groove of the mandibular

**Figure 10** 1st maxillary permanent molar occludes with the mesial groove of the mandibular 1st permanent molar (Class I molar relation) and all the posterior teeth fit with each other with an overjet and overbite of 2 mm each in the anterior teeth

**Figures 11A to D** Skeletal Class I malocclusion. (A and B) Straight profile; lips competent; (C and D) Angle Class I molar relation with normal overjet and overbite with mild crowding

**Figures 12A to D** Skeletal Class II malocclusion. (A and B) Retrognathic mandible, convex facial profile, incompetent lips, lip trap, deep mentolabial sulcus; (C and D) Proclined incisors, increased overjet and overbite, Class II molar relation

**Figures 13A to E** Skeletal Class III malocclusion. (A to C) Prognathic mandible, concave profile, chin protruding, midface flatness; (D and E) Reverse overjet and overbite, Class III molar relation

1st permanent molar. There is reverse overjet and underbite. The maxilla and mandible are not in harmony with each other. Either the maxilla is retrognathic or mandible prognathic or there is a combination of both. The facial profile is concave, the midface being flat and the chin is protruding. The profile of face makes individuals very conscious of their appearance (**Figs 13A to E**). This malocclusion also has skeletal component in addition to the dental component.

## Treatment of Malocclusion

### Deciduous Dentition Phase

Very few conditions require orthodontic treatment in this phase. Class III malocclusion where there is cross bite of anterior or posterior teeth can lead to restriction of normal growth of maxilla and hence aggravate the malocclusion. Such malocclusion should be intercepted and treated when diagnosed. Certain deleterious habits such as prolonged thumb sucking can lead to proclination of teeth and can develop into class II malocclusion. Such habits can also lead to developing of an open bite (**Figs 14A and B**). In this phase, the habits are intercepted by appropriate habit breaking appliances.

### Mixed Dentition Period

The developing malocclusion can be intercepted and treated using oral appliance that take the advantage of the neuromusculature to correct malocclusion and also direct the growth of jaws to favorable direction to minimize malocclusion. These are referred to as myofunctional appliances (**Figs 15A and B**).

### Permanent Dentition

Till the age of 11–12 years in girls and up to 14 years in boys, the myofunctional appliance and the fixed orthodontic braces are used to treat the malocclusion, especially when the skeletal component is also present. The appliance takes the advantage of growth and redirects the deficient or excess mandible or maxilla to normal. The only dental component malocclusion is treated using fixed

**Figures 14A and B** (A) Thumb sucking habit; (B) Open bite, the gap between upper and lower incisors

orthodontic appliances as braces on teeth. The treatment typically requires wearing braces and wires for 18–24 months and retention periods of 12 months or more (**Fig. 16**).

## ANOMALIES OF DENTOFACIAL REGION: DEVELOPMENTAL DISORDERS OF TONGUE

### Macroglossia

Macroglossia or enlarged tongue can be due to a variety of causes. It has been traditionally defined as a resting tongue that protrudes beyond the teeth or alveolar ridge. Broadly it can be classified as true macroglossia or pseudomacroglossia. True macroglossia is either secondary to hyperplasia or hypertrophy of tongue muscles or can be as a result of infiltration by other tissues. Pseudomacroglossia is the relative enlargement of tongue seen due to a small mandible. Some of the causes of macroglossia are specified in **Table 3**.

### Clinical Features

A large tongue is usually obvious in comparison to adjacent structures (**Fig. 17**). The child may show crenations along the lateral border of tongue due to indentations of teeth. Speech can be

**Figures 15A and B** Myofunctional appliance—"Twin Block" consisting of mandibular and maxillary components to be worn accordingly

**Figure 16** Fixed orthodontic appliance

**Table 3** Some causes of macroglossia

<i>Congenital</i>	<i>Acquired</i>
Congenital hypothyroidism	Acromegaly
Down syndrome	Lingual thyroid
Beckwith-Wiedemann syndrome	Amyloidosis
Lymphangiomas	Angioedema
Mucopolysaccharidoses	Tumors infiltrating the tongue
Neurofibromatosis	

affected due to the enlarged size. There may be drooling of saliva, difficulty in swallowing with limited mobility of tongue. Constant protrusion of tongue may lead to ulceration. Dental abnormalities may accompany like anterior open bite. Some patients may present with airway obstruction, noisy breathing, stridor and it may be a cause of obstructive sleep apnea syndrome.

### Diagnosis

Thorough history and physical examination is required, which may allow the recognition of a syndrome of which the enlarged tongue is one component. Thyroid function tests, isotopic imaging of the thyroid gland, chromosomal studies, and urinary mucopolysaccharide assay may be indicated. Computed tomography and magnetic resonance imaging may be useful to delineate soft tissues and to show the extent of tumors and other masses. Microscopic examination of tongue tissue in primary macroglossia may be unhelpful, but biopsy is useful for localized

**Figure 17** Macroglossia in a patient with mucopolysaccharidoses

lesions of the tongue that occur in chronic granulomatous and neoplastic disorders.

### Treatment

Reduction glossectomy is required in cases of true primary macroglossia if it interferes in function. Treatment of other infiltrative tumors requires excision. Goal is to restore tongue size and thereby improve function.

### Tongue-Tie

Ankyloglossia or tongue-tie is the restriction of free tongue movement caused due to attachment of the inferior frenulum to the bottom of the tongue (**Fig. 18**). It has a wide spectrum of presentation ranging from very thin band to fully developed ankyloglossia. Reported incidence of tongue-tie varies from 0.04% to 0.1% and the male:female ratio is 2.6:1.

Limitation of tongue mobility beyond the incisal edges of anterior teeth is the defining feature. Limited tongue movement can lead to breastfeeding problems causing sore nipples, repeated bouts of mastitis, and failure to thrive. Speech defects especially with articulation of sounds like l, r, t, d, n, th, z is seen because pronunciation of these requires opposition of tongue to alveolus or palate. Inability to perform internal oral toilet and inability to lick lips is also seen. It may cause dental anomalies like persistent gap between incisor teeth. Treatment consists of frenulectomy.

**Figure 18** Tongue-tie

### Lingual Thyroid Nodule

Thyroid gland originates from the endodermal tissues in the pharyngeal floor between the tuberculum impar and hypobranchial eminence. The thyroid then descends along a path from the foramen cecum to its final position in front of the trachea. While descending it retains its communication with the foramen cecum which is known as the thyroglossal duct. The duct gradually degenerates in most individuals. The lingual thyroid is an anomalous condition in which thyroid follicles are found in the substance of the tongue possibly from a thyroid anlage which failed to migrate to its normal position. The incidence of lingual thyroid is reported as 1:100,000 with male: female ratio of 1:7.

### Clinical Features

The lingual enlargement is usually seen in the midline, at the base of the tongue. It is usually deeply seated rather than a superficial exophytic lesion. Onset of symptoms is usually early in life and it may present as dysphagia, dyspnea, dysphonia, sleep apnea, and stridor. It may be a cause of respiratory emergency with severe airway obstruction. Patients may show features of hypothyroidism and in some it may be the only thyroid tissue in the body.

### Diagnosis

Neck palpation is necessary to check for normal thyroid tissue. Investigations required are: thyroid function tests (for baseline thyroid function) and technetium scanning (demonstration of thyroid tissue in the tongue and normal thyroid gland). Fine needle aspiration cytology of the mass demonstrates thyroid tissue and may be helpful in differentiating from salivary gland tumors.

### Treatment

Suppressive therapy with exogenous thyroid hormone should be tried first. This often decreases the gland size after which elective surgery can be planned if required. Levothyroxine therapy should be initiated after surgical excision as the lingual thyroid may be the only thyroid tissue in the body.

## DEVELOPMENTAL DISORDERS OF GINGIVA

### Fibromatosis Gingivae

#### (Hereditary Gingival Fibromatosis)

It is a benign, idiopathic condition causing diffuse fibrous overgrowth of gingival tissues. It is usually autosomal dominant and affects males and females equally. The reported incidence is

**Figure 19** Hereditary gingival fibromatosis

of 1:350,000. Gingival fibromatosis may be familial or idiopathic. The familial variation may occur with a number of other inherited syndromes, e.g., Zimmerman Laband syndrome, Cowden syndrome, juvenile hyaline fibromatosis, multiple hamartomas, and tuberous sclerosis.

### Clinical Features

Gingival enlargement is usually slowly progressive, sometimes covering the major parts or even complete tooth surfaces which may project into the vestibule and floor of the mouth (**Fig. 19**). It can interfere with normal mastication and even lip closure that makes speech difficult. The enlarged gingival tissue appears firm and pink and may either be generalized (symmetric) or localized (nodular). Severity varies in patients and it may completely involve the buccal and lingual tissues of both maxillary and mandibular arches. Hereditary gingival fibromatosis (HGF) is seldom present at birth. It usually begins at the time of eruption of permanent dentition but can develop with the eruption of primary dentition. If the enlargement is present before tooth eruption the dense fibrous tissue may interfere with or prevent eruption. The most common effects related to gingival overgrowth are spacing between teeth, malpositioned teeth and prolonged retention of primary teeth.

### Treatment

Surgical removal of excessive tissue and exposure is indicated when it interferes in eruption of teeth and for cosmetic purposes.

## DEVELOPMENTAL DISORDERS OF TEETH

### Anodontia/Hypodontia

Anodontia or congenital absence of teeth may be either total or partial. Total anodontia, i.e., complete absence of dentition is an extremely rare condition which can affect either deciduous or permanent dentition. It usually is seen with a more generalized disorder like hereditary ectodermal dysplasia. Partial anodontia (hypodontia/oligodontia) which involves one or more teeth is common. Mandibular third molars followed by maxillary third molars are the most common missing teeth. Other commonly missing teeth include maxillary lateral incisors and mandibular second premolars. Hypodontia in deciduous dentition is however uncommon. The etiology of single missing tooth is unknown and familial tendency may be seen. Treatment is usually prosthetic replacement for the missing tooth in permanent dentition.

### Supernumerary Teeth

Presence of an *extra-tooth* beyond the normal number of teeth in the dentition is termed as supernumerary tooth. Not unusual these are more common in the permanent dentition. The etiology is unknown. The incidence is around 2.1% in the permanent dentition and 0.8% in the deciduous dentition. These may be single,

**Figure 20** Amelogenesis imperfecta

multiple, unilateral, bilateral affecting either arches. Multiple supernumerary teeth are seen associated with conditions like cleft lip and palate, cleidocranial dysplasia, and Gardener syndrome. Common types of supernumerary tooth include: Mesiodens—a single cone-shaped tooth usually found between or palatal to maxillary central incisors; paramolars—a 4th molar seen distal or buccal to maxillary molars. Treatment is usually extraction.

### Amelogenesis Imperfecta

Dental enamel is a highly mineralized tissue with over 95% of its volume occupied by unusually large, highly organized, hydroxyapatite crystals. Congenital defects of this layer leads to an anomaly known as amelogenesis imperfecta. The reported incidence varies widely from 1:700 to 1:14,000. This congenital anomaly shows autosomal dominant, autosomal recessive, sex-linked and sporadic inheritance patterns. It may as well present as a sporadic case. The structure and clinical appearance of enamel of all or nearly all the teeth is affected in a more or less equal manner. The enamel may be hypoplastic, hypomineralized or both and teeth affected may be discolored, sensitive or prone to disintegration either posteruption (posteruptive breakdown) or pre-eruption (idiopathic resorption) (**Fig. 20**). Extraoral radiographs may reveal the presence of unerupted and sometimes spontaneously resorbing teeth. Intraoral radiographs will reveal the relative contrast between enamel and dentine in cases where mineralization may have been affected. Treatment is limited to improving cosmetic appearance.

### Enamel Hypoplasia

Enamel hypoplasia is defined as an incomplete or defective formation of the organic enamel matrix of the teeth. Broadly, it can be classified as either hereditary (amelogenesis imperfecta) or environmental. Hereditary form involves both deciduous and permanent dentition and is restricted to defects of only the enamel. The environmental form on the other hand involves either dentition and both enamel and dentin are affected. Hypoplasia occurs only if injury occurs during the formative stages of tooth. Once enamel has been formed no such defect is seen. Causes of injury to teeth are listed in **Box 1**.

#### BOX 1 Causes of injury to teeth

- Nutritional deficiencies—vitamin A, C and D
- Exanthematous diseases—measles, chickenpox, scarlet fever
- Congenital syphilis
- Hypocalcemia
- Birth injury, Rh hemolytic disease
- Local infection or trauma
- Chemicals: Tetracycline, Fluorides
- Idiopathic.

Use of tetracycline in childhood can chelate calcium of developing tooth. It becomes incorporated in the enamel resulting

**Figure 21** Yellowish spots of enamel hypoplasia seen on maxillary central incisors

in characteristic staining of teeth. While 1 ppm of fluoride in drinking water is known for its anticariogenic effect on teeth, excessive fluoride in water leads to enamel hypoplasia (enamel mottling). Indian states of Rajasthan and Haryana have high fluoride content in their groundwater hence enamel fluorosis is common in these states. The severity of hypoplasia increases with increase in fluoride content.

### Clinical Features

Hypoplastic teeth depending upon severity show occasional white flecking or spotting of enamel to more white opaque areas covering the entire tooth surface (**Fig. 21**). Severe cases show pitting, brownish staining of the tooth surface and may have a corroded appearance. The affected teeth have high rate of wear and tear and are prone to fractures.

### Treatment

Cosmetic dental treatment is required depending upon involvement.

## DEVELOPMENTAL DISORDERS OF ERUPTION

### Premature Eruption

A wide variation exists in the eruption age of deciduous and permanent teeth and sometimes deciduous teeth that have erupted into the oral cavity are seen in infants at birth. These are natal teeth. Neonatal teeth are those which erupt in the first 30 days of life. The mandibular central incisors are the usual ones to erupt. The etiology of this phenomenon is however unknown.

### Delayed Eruption

Absence of deciduous teeth beyond the maximal limit may result in conditions like rickets, cretinism and cleidocranial dysplasia. It may be completely idiopathic in some cases. Local factors like gingival fibromatosis may also lead to delayed eruption.

### Embedded and Impacted Teeth

Embedded teeth are those which do not erupt due to an inherent lack of eruptive force. Impacted teeth on the other hand are prevented from erupting by a physical barrier in the eruption path. Lack of space due to crowding of dental arches; premature loss of deciduous teeth with subsequent closure of space are some of the common causes of impacted teeth. Mandibular third molars (**Fig. 22**), maxillary third molars and maxillary and mandibular canines (**Fig. 23**) are most commonly impacted. Impacted tooth may cause disruption of eruption paths of adjacent teeth and can lead malocclusion. While impacted third molars other

**Figure 22** Impacted mandibular third molar

**Figure 23** Impacted left mandibular canine

**Figure 24** Mandibular micrognathia secondary to temporomandibular joint ankylosis

deeply impacted teeth are usually extracted, others may require orthodontic treatment for their eruption and repositioning.

## DEVELOPMENTAL DISTURBANCES OF THE JAWS

### Micrognathia

Micrognathia simply means a small jaw (**Fig. 24**). This may involve either the maxilla or mandible. True micrognathia needs to be differentiated from apparent micrognathia where the

defect lies in the position of the jaw rather than in size of the jaw. True micrognathia can be classified as congenital or acquired. Congenital mandibular micrognathia seen in syndromic patients like Pierre Robin sequence, Treacher Collins syndrome, Stickler syndrome, and Nager syndrome or may be seen in rare cases of condylar agenesis. In India and many other developing countries, acquired micrognathia is usually secondary to temporomandibular joint (TMJ) ankylosis. Micrognathia of the maxilla occurs due to deficient maxillary development and is most commonly due to cleft lip/palate. It may also be seen in patients with achondroplasia, Crouzon syndrome, etc.

### Clinical Features

The mandible appears to be repositioned relative to the maxilla in cases of mandibular micrognathia. In severe cases, bird-face deformity may be seen.

- In cases of maxillary retrognathia, the middle-third of the face appears retracted.
- Mandibular micrognathia cases may be associated with obstructive sleep apnea syndrome. The retruded mandible results in retroglossal airway obstruction which may result in desaturation episodes in the patient. Snoring and excessive day time sleepiness are characteristics signs of obstructive sleep apnea.
- Maxillary retraction may result in airway obstruction at the level of nasal passage. Speech may be affected.

### Temporomandibular Joint Ankylosis

Temporomandibular joint ankylosis is the most common cause of acquired mandibular micrognathia in India. It results due to fibrous or bony union of the mandibular condyle to the glenoid fossa. Other causes include *trauma*: direct or indirect injury to the mandibular condyles; *infections*: otitis media, mastoiditis, parotitis; *birth injury*: forceps delivery resulting in injury to mandibular condyles; and *others*: rheumatoid arthritis, infectious arthritis, Marie-Strumpell disease.

### Clinical Features

Condition occurs at any age but most cases are seen in children. Patient with fibrous ankylosis usually has some amount albeit decreased mouth opening. In complete ankylosis however the mouth opening is nil. In unilateral ankylosis, the chin is deviated to the affected side and face appears asymmetric. There is flattening on the nonaffected side with soft tissue fullness on the affected side. The movement of the condyle on the affected side is not palpable. Malocclusion may be present. In bilateral ankylosis, the chin is retruded with a characteristic convex profile. Condylar movements are not palpable bilaterally. Patients may have poor oral hygiene and multiple carious teeth due to limited mouth opening. Nutrition may be hampered in long standing cases.

### Radiographic Features

Abnormal or irregular shaped condyle with radiopacity filling the joint space is evident on orthopantomogram.

### Treatment

Treatment of TMJ bony ankylosis is surgical. Arthroplasty of the affected joint is carried out to provide a sufficient gap between the two bony surfaces. In case there is concomitant underdevelopment of the jaw, distraction osteogenesis for lengthening of the mandible can be performed.

### Macrognathia

Macrognathia means large jaws. Sometimes, increase in the size of the jaws is not in proportion to the growth of the entire

**Figure 25** Macrognathia of maxilla secondary to fibrous dysplasia

skeleton. Macrognathia may be associated with certain conditions, such as Paget's disease, acromegaly, and fibrous dysplasia of the jaws (**Fig. 25**). It is a rare condition in children. One condition which is frequently seen is mandibular prognathism. In many cases mandibular prognathism is due to disparity in the size of the maxilla in relation to mandible or due to excessive condylar growth.

### *Treatment*

Treatment depends on the underlying cause. In case of fibrous dysplasia, surgical contouring is performed only after the completion of growth. Mandibular prognathism can be treated by growth modulation and orthodontic correction of the malocclusion if diagnosed at an early age.

### IN A NUTSHELL

1. Three distinct phases of tooth development are recognized namely: deciduous dentition, mixed dentition, permanent dentition.
2. Deciduous dentition stage is between 6 months and 6 years of age, mixed dentition from 6 years to 12 years and permanent dentition from 12 years onwards.
3. Mixed dentition stage is of particular interest as it may herald the onset of malocclusion and provide for its interception and correction.
4. Eruptions times of teeth vary with individuals and close follow-up with dentists is essential to intercept any developing anomalies.
5. Malocclusions should be treated for esthetic and functional reasons.
6. Tongue-tie is a common anomaly in children which may affect speech development and cause dental spacing. It is treated by frenulectomy.
7. White chalky spots on dentition are usually a sign of enamel hypoplasia, a very common condition due to high fluoride content in drinking water.
8. Micrognathia is mostly acquired and secondary to temporomandibular joint ankylosis. Bird facies due to small mandible, convex profile are usual features of mandibular micrognathia.
9. Obstructive sleep apnea is seen in a certain cohort of children suffering from temporomandibular joint ankylosis and extreme micrognathia.

## Chapter 19.5

# Bone Age and Predicted Final Height

*M Vijayakumar, Anju Seth*

In normal children, there is an orderly and predictable sequence of appearance and development of epiphyseal centers in growing bones, which can be readily observed on a radiograph. This has enabled generation of standards for bone maturation at different ages during childhood and adolescence for both genders. Comparison of skeletal maturity of an individual with these age and gender-related standards forms the basis of bone age (BA) assessment. Importance of BA lies in the fact that it is a better indicator of biological maturity as compared to the chronological age (CA), and many parameters including height velocity, menarche, accrual of muscle mass and bone mineral density correlate better with BA than CA. Assessment of BA is thus an important tool in evaluation of various types of growth, endocrine and genetic disorders and to assess the impact of treatment in these conditions.

### BONE DEVELOPMENT

Flat bones like carpal bones develop from a single primary center. In contrast, long bones like radius and ulna and short bones like metacarpals have a primary center which will develop into the diaphysis and a secondary center that appears at the end of the bone which forms the epiphysis. The part of diaphysis that lies close to the epiphysis is the metaphysis. Growth of the bone ceases and final adult stature is attained when osseous structures of metaphysis and epiphysis fuse.

The process of bone calcification begins as early as 8th week of intrauterine period. By 13th week of fetal life, most of the primary centers of long bones are well developed into diaphysis which gets completely ossified at birth. Epiphysis for calcaneus and talus appear by 6 months in utero and that of cuboid by birth. Ossification of distal femoral epiphysis begins by 38 weeks in utero and that of proximal tibial epiphysis by 40 weeks of gestation. Ossification center of head of femur appears by 1 year of life. Many factors may influence the normal maturational pattern of bones. These include genetic factors, hormones (thyroxine, growth hormone and sex steroids) and nutrition.

### ASSESSMENT OF SKELETAL MATURITY

Radiographs of entire skeleton may appear a logical tool to assess BA, but are neither practical nor, fortunately required. For clinical purposes, beyond the neonatal period, radiograph of the left hand and wrist is adequate, and is commonly employed for BA assessment since changes associated with progressive skeletal maturity are reasonably reflected in a radiograph of the hand.

### Normal Sequence of Skeletal Development Observed on a Radiograph of Hand

First ossification center that appears in the X-ray of hand and wrist is that of capitate, closely followed by hamate at 3 months of age. At about 1 year in girls and 1½ years in boys, ossification center in the distal epiphysis of radius appears. Between 1 year and 3 years of age ossification centers of metacarpals and phalanges develop.

Boys tend to lag behind girls by 6 months during this period. The third carpal bone (triquetral) develops by 2 years in girls and 6 months later in boys. Subsequently, ossification centers of other carpal bones appear in the following order:

- Lunate (3 years in girls, 6 months later in boys)
- Trapezium (4 years in girls, 6 months later in boys)
- Trapezoid (5 years in girls, 6 years in boys)
- Scaphoid (6 years in girls, 7 years in boys).

Distal epiphysis of ulna also appears during this period (5 years in girls, 6 years in boys). During early puberty, pisiform (9 years in girls, 10 years in boys) and sesamoid in the tendon of abductor pollicis appear (11 years in girls, 12 years in boys). During this period epiphysis of metacarpals and phalanges continue to grow and their width become more than the metaphysis. As the puberty advances, progressive fusion of epiphysis to metaphysis occurs in the long bones, which begin in the phalanges and metacarpals. Epiphyseal fusion of ulna followed by radius occurs at 15–17 years in girls and 17–19 years in boys.

### Obtaining a Radiograph for Bone Age Assessment

Correct positioning of the hand and wrist while obtaining the radiograph is important since incorrect positioning may give an inaccurate image of the bone's shape and obscure the new changes that have occurred in it during maturation. The hand should be placed with palm facing downwards in contact with the cassette. Axis of the forearm should be in direct line with the axis of the middle finger. Upper arm and forearm should be in the same horizontal plane. Fingers should not be touching each other and thumb should be placed at an angle of 30 degrees with the first finger. X-ray tube should be kept half way between the tip of the fingers and distal end of the radius (above the head of third metacarpal). Tube film distance should be 30 inches.

### Methods for Assessment of Skeletal Age

Bone age is assessed by comparing the degree of maturation of various epiphyses in the X-ray of the hand with age-related standards. As the age advances, so does the variability in time of appearance and fusion of centers. Thus, mere assessment of appearance and fusion of centers is a crude method of BA assessment and has limited clinical utility. In clinical practice, Greulich and Pyle (GP) atlas, based on visual evaluation of skeletal development of left hand and wrist, is a commonly used method for assessment of BA. This method was introduced in 1950 and remains the most widely used method even now. Tanner Whitehouse method (TW) is the other frequently used method. In this electronic era, attempts are also being made to develop digital methods to assess the bone age quickly and accurately. In all methods, different reference standards exist for boys and girls.

### Greulich and Pyle Atlas

This atlas is divided into two separate set of X-rays, one for boys and the other for girls. Each part contains radiographs of left hand arranged in chronological order. BA of a given child is assessed by comparing his/her radiograph with the standards given in the atlas. To begin with, the X-ray is compared with the X-ray picture of the same age and gender given in the atlas. If it does not match correctly, comparison is made with the radiographs preceding or following that radiograph till the closest match is achieved. If none of the X-rays in the atlas correlate with the given X-ray, BA is interpreted as the picture to which it closely resembles. If the X-ray falls in between two pictures in the atlas, the age is interpreted to be between the ages of the standards it closely resembles.

### Tanner and Whitehouse Method

This method is based on individual bone's stages of maturity. Recently the updated version, TW3 is in use. Here, 20 regions of interest (ROI) in different bones are considered for BA calculation. Each ROI is divided into discrete stages depending on their development and each stage is given a letter (A, B, C, D, E, F, G, H and I). A numerical score is assigned to each stage. By adding the scores of each ROI a maturity score is obtained. This score is compared with the provided charts (separate for boys and girls) and BA is determined. Though time consuming, TW method gives a more objective assessment of BA as compared to GP atlas where there are more chances of interobserver variation in interpretation. Further, TW3 can differentiate BA up to 1/10th of a year; while GP atlas gives a rough approximation with interval of 6–12 months between standards. TW3 method is thus more sensitive in following small changes in BA.

### Computer-assisted Skeletal Age Scores

Recently, various computer-assisted techniques for BA assessment have been developed. In these methods, the hand radiograph is digitized, bone by bone. Each digitized information is analyzed by comparing with digitized images of standard stages (A to I) and the closest match is found. The actual rating is done by the computer. Commonly used methods are computer-assisted skeletal age score (CASAS) and BoneXpert.

### Clinical Applications

Bone age assessment provides important clues in diagnosis of various growth disorders. Degree of delay in BA may reflect duration of disease process. BA helps in predicting adult height and to monitor growth potential over time, especially if a treatment to modify growth/puberty is being given. BA is delayed in short stature due to chronic systemic diseases, malnutrition, constitutional delay in growth and puberty (CDGP), and various endocrine disorders including growth hormone deficiency and hypothyroidism. It is not generally delayed in skeletal dysplasia since epiphyseal maturation in these disorders remains unaffected. BA is advanced in congenital adrenal hyperplasia, precocious puberty and in overgrowth syndromes like Beckwith-Wiedemann syndrome.

### Short Stature

Bone age is an important tool in the diagnosis of short stature. Familial short stature is characterized by BA corresponding to CA or delayed by less than a year. Mild delay (up to 2 years) is commonly seen in malnutrition, systemic diseases and idiopathic short stature. In constitutional delay in growth and puberty (CDGP), BA is usually delayed by 2–3 years though it correlates well with height and age. Endocrine disorders like hypopituitarism and hypothyroidism, on the other hand, are characterized by marked delay in BA, even more than that expected for height. BA is also useful for assessing response to treatment in these disorders, e.g., during growth hormone therapy. If increment in height during treatment is larger than increment in BA, it predicts improved prognosis for final stature.

### Pubertal Disorders

Exposure to sex hormones accelerates bone maturation. BA is delayed in almost all cases with delayed puberty, while precocious puberty is characterized by marked BA advancement. In normal pubertal variants like premature thelarche and adrenarche, BA advancement is minimal. Serial BA assessment, at least once every year, is recommended during follow-up evaluation of subjects receiving gonadotropin-releasing hormone analog

therapy for precocious puberty to assess improvement in predicted height, and to help decide duration of therapy. Slowing of bone maturation on therapy is a sign of adequacy of treatment.

### Congenital Adrenal Hyperplasia

Adrenal androgens have a marked stimulatory effect on bone maturation. This accelerated bone maturation eventually leads to premature closure of sutures resulting in final short stature. BA assessment is an important component of follow-up evaluation of children with congenital adrenal hyperplasia (CAH). This helps in titrating the dose of corticosteroids and prediction of final adult height. Inadequate drug dosage results in rapid advancement of BA age due to unsuppressed sex steroid production.

### PREDICTION OF ADULT HEIGHT

In a normal individual, there is a direct relation between degree of skeletal maturation and time of epiphyseal closure, an event that marks attainment of adult stature. Therefore, there is a significant correlation between BA and the proportion of final stature achieved. More delayed the BA for CA, longer the time before epiphyseal fusion. On the other hand, if the BA is advanced, epiphyseal fusion and attainment of final stature would occur earlier than at the expected CA. Expected adult height can be predicted from a child's height at a particular age and his skeletal age at the time of obtaining the height. Various methods have been developed to assess this, like those by Bayley-Pinneau, Roche, or TW.

The method formulated by Nancy Bayley and Samuel Pinneau is based on GP atlas. Here height of the child at maturity is taken as 100% and the average percent of mature height (PMH) for various bone ages are precalculated and presented as separate charts for boys and girls. Mature height is calculated by dividing the child's height by the percentage of mature height which corresponds to his/her BA. Prediction is generally more accurate if the difference between BA and CA is not much.

In the method formulated by JM Tanner and RH Whitehouse, coefficients of height, age and BA are presented for boys and girls of different chronological ages. Accurate height and CA are recorded and BA is calculated by TW3. Predicted adult height can be derived from the following formula:

$$\text{Predicted adult height} = (\text{Height coefficient} \times \text{present height in cm}) + (\text{Age coefficient} \times \text{chronological age}) + (\text{Bone age coefficient} \times \text{Bone age in years}) + \text{constant}$$

There are separate charts for boys and girls. It should be realized that regardless of method used, height predictions are not totally accurate and of limited clinical use in children with growth disorders. One of the main sources of inaccuracy is impreciseness in BA assessment. A small difference in BA estimation can lead to a marked difference in predicted height. Their main clinical application remains in assessing short-term response to various growth modifying therapies.

### IN A NUTSHELL

1. Bone age is a better indicator of biological maturity as compared to the chronological age.
2. Assessment of bone age is an important tool in evaluation of growth, endocrine and genetic disorders and to assess the impact of treatment in these conditions.
3. It also helps in predicting adult stature of a child.
4. Bone age is assessed by comparing the degree of maturation of various epiphyses in the X-ray of the hand with age-related standards. Common methods in clinical use include Greulich and Pyle atlas and Tanner and Whitehouse method.

## Chapter 19.6

# Failure to Thrive

Sudha Rao Chandrashekhar

Although regular assessment of growth and monitoring of growth parameters are important aspects of child health surveillance programs, detecting deviations from normal especially in infants and young children is a major challenge to practicing pediatrician and primary care physicians. Divergence from normal may occur at any age, in any of the parameters and in any direction. Hence routine measurement and maintaining a longitudinal record of growth parameters especially weight, length/height and head circumference in all children especially in early childhood, forms the biological basis of early detection of any abnormality.

Failure to thrive (FTT) is a description of any condition associated with inadequate growth or inability to maintain adequate growth especially in early childhood, commonly in the first 2 years of life due to lack of sufficient *usable* nutrition contributed by biological, environmental and psychosocial factors. Thus FTT is not a diagnosis by itself but is a sign that has multiple etiologies with long-term effects on stature, development and cognitive functions.

### DEFINITION

In routine practice, FTT is best defined as poor physical growth diagnosed by observation over a period of time using reference growth charts. Although anthropometric criteria form the basis of defining FTT, there is no consensus on the definition. Use of a single parameter like weight has been shown to have low positive predictive value for true undernutrition. It is thus suggested to use more than one criterion to define FTT.

FTT can be defined if any of the following criteria are met on multiple occasions on follow-up:

- Weight for age less than 5th percentile
- Weight deceleration crossing two major percentile lines
- Weight velocity less than 5th percentile
- Weight less than 75% of median weight for age
- Weight less than 75% of median weight for length
- Length for age less than 5th percentile
- Body mass index (BMI) less than 5th percentile for age and gender.

In any nutritional deficiency state, weight gets affected earlier and to a greater extent as compared to linear growth or growth of head circumference which get affected with severe or prolonged nutritional deprivation.

As weight is accepted as the simplest and most reasonable marker of FTT, the condition has been now renamed as *weight faltering*. FTT/weight faltering is commonly defined as weight less than 5th percentile for age on two or more occasions and/or weight crosses two major percentile lines over time. Weight faltering is again a description of a growth pattern rather than a disorder. If we look at normal growth pattern 5% of all children will fulfil the above criteria of weight faltering and thus may be labeled FTT causing not only anxiety amongst parents and caretakers but also initiating interventions where none may be required for most children.

### ASSESSMENT OF GROWTH

Accurate measurement of weight and height/length, head circumference on multiple visits and plotting on standardized growth curve is essential for defining FTT.

The technique of measurement of the various anthropometric parameters and their interpretation using an appropriate growth reference has been already described in the chapter 19.3 on assessment of physical growth. In children born premature, the anthropometric parameters should be plotted at corrected chronological age, calculated as postnatal age at examination minus number of weeks born premature. For example, a baby born at 32 weeks gestational age is 8 weeks premature (40–32) and at 9 months of chronological age the corrected age would be 7 months (9–2 months). There is no consensus as to how long to correct for the prematurity as the catch-up growth is dependent on degree of prematurity, chronological age at assessment, genetic potential, ethnicity, etc. Most experts prefer to correct for prematurity till 18 months of age for head circumference, 24 months of age for weight and 40 months of age for stature. It is expected that more premature a baby, the catch-up growth would continue for a longer period of time. In UK, it is accepted to correct for prematurity all the three parameters namely weight, height/length and head circumference till 2 years of chronological age for children born before 32 weeks of gestation and until 12 months of chronological age for babies born between 32 weeks and 36 weeks gestation. Despite correction for prematurity when a child remains small, assessment of velocity of growth for corrected age or weight for length/height helps as they would be as per normal reference standard. The expected rate of daily weight gain at different ages is given in **Table 1**.

Another aspect of growth in infancy which confounds the definition of FTT is the normal variation in growth seen in the first 2 years of life. Some children may show a *catch-down* in growth as per their genetic potential, in the first 2 years of life. Although they initially shift major percentile lines in terms of weight and/or length, they continue to show a normal growth velocity subsequently. Babies born to short parents, large for gestational age newborns and those with constitutional delay, may show this physiological downward deviation from their birth centile. Thus, interpretation of growth in these children should be done on a longitudinal basis and in the correct perspective.

**Table 1** Expected daily weight gain at different ages

Age	Expected daily weight gain (g/day)
0–3 months	26–31
3–6 months	17–18
6–9 months	12–13
9–12 months	9–13
1–3 years	7–9

### EPIDEMIOLOGY

The prevalence of FTT is dependent on the definition, the reference standard used, the population studied, the demography of the population sample whether rural or urban and whether studied in in-hospital setting or primary care setting.

Nearly 80% of children with FTT present in the first 18 months of life. In the US, FTT is seen in 5–10% of children in primary care setting and 3–5% of children in hospital setting. In India as per the National Family Health Survey-3 (NFHS-3, 2005–2006) using World Health Organization growth standards, 22.9% children under 3 years are wasted with a higher prevalence in rural (24.1%) as compared to urban (19.1%) areas. There seems to be an increase in number of children who are wasted as compared to NFHS-2 (1998–1999) where 19.7% children under 3 years were reported as wasted.

Failure to assess growth parameters, incorrect measuring technique and faulty plotting or interpretation may lead to failure to correctly detect FTT in many children. In a study from UK, 54% children with FTT were undiagnosed by the primary care physicians and a diagnosis was delayed in 41% due to incorrect plotting of growth parameters. In some population series, nearly 33% children with FTT were undiagnosed. This is usually due to poor physician awareness, motivation and lack of time to assess growth parameters in a busy clinic.

## ETIOLOGY

The etiology is multifactorial with interplay of biological, environmental and psychosocial effects. The traditional etiological classification of FTT as organic or nonorganic is no longer exclusive as there is often a significant overlap between the two conditions and they may coexist. A child with an organ system disease as a cause of FTT could have an associated psychological affecter caused by poor parenting due to stress. As the underlying pathology is nutritional deficiency, it is prudent to classify FTT based on calorie deficit as due to inadequate intake, improper or poor absorption, and increased requirement due either to increased metabolism or defective utilization (**Table 2**).

Inadequate calorie intake is the most common cause of FTT. In Indian scenario poor calorie intake is often due to lack of availability of nutrients due to poor purchasing capacity or inadequate knowledge of appropriate feeding. Organic causes that limit the food intake while increasing the caloric requirement, especially recurrent respiratory infection, recurrent diarrhea, infections like tuberculosis and human immunodeficiency virus (HIV) are important contributors to causation of FTT.

*Environmental enteropathy* (tropical enteropathy), a recently recognized entity causing FTT is caused by poor hygiene and sanitation. In the presence of unhygienic environment, there is a constant orofecal contamination leading to repeated episodes of diarrhea which is sometimes self-limiting. Repeated gastrointestinal (GI) infection leads to mucosal inflammation and structural changes in small intestine resulting in mucosal disruption causing malabsorption, altered mucosal immunity causing repeated infections—a vicious cycle leading to malnutrition and FTT. In a study from Vellore, environmental enteropathy was found in babies as young as 8 weeks of age.

Psychosocial causes of FTT are also increasingly recognized in Indian scenario. Poor parenting skills, lack of knowledge of calorie rich diets, single parent, stress of living, substance abuse (alcohol, tobacco and drugs) and child abuse are not uncommon especially in urban population.

**Table 2** Etiology of failure to thrive

<i>Inadequate calorie intake</i>	<i>Inadequate calorie absorption</i>
<b>Poor feeding</b> Breastfeeding problems Incorrect formula/top milk feeds Inadequate number of feedings per day Underfeeding (lack of food/lack of knowledge) Difficulty/delayed weaning Food faddism Misreading signals of satiety/hunger Coercive feeding Autonomy struggle Highly distractible child/environment Neglect, abuse, parental mental illness <i>Neurological dysfunction:</i> Oromotor dysfunction, sensory based feeding disorder, autism, swallowing difficulty Gastroesophageal reflux disease (GERD)	<b>Malabsorption syndromes</b> Chronic diarrhea Frequent vomiting Environmental enteropathy Celiac disease Cystic fibrosis Pancreatic insufficiency Protein-losing enteropathy Chronic liver disease Short gut syndrome Inborn errors of metabolism
<b>Psychosocial causes</b> Poverty Social isolation, stresses in life Single parent, poor parenting skills, parental cognitive problems Substance abuse, physical abuse Psychopathy Poor child-parent interactions	<b>Food allergy/intolerance</b> Milk protein allergy
	<b>Intestinal parasites</b>
<i>Excess calorie expenditure due to increased requirement*</i>	<i>Excess calorie expenditure due to defective utilization*</i>
<b>Systemic illnesses</b> <i>Cardiac:</i> Cyanotic/acyanotic heart disease, congestive cardiac failure, vascular anomalies <i>Pulmonary:</i> Chronic lung disease, severe asthma, chronic respiratory failure, hypoxia <i>Renal:</i> Chronic renal failure, renal tubular acidosis <i>Endocrine:</i> Hyperthyroidism, diabetes mellitus, diabetes insipidus, adrenal insufficiency, growth hormone deficiency <i>Infections:</i> Tuberculosis, human immunodeficiency virus (HIV), congenital infections <i>Others:</i> Malignancy, systemic inflammatory disorders	<b>Chromosomal disorders</b> Trisomy 13, 21, 18 <b>Dysmorphic/Genetic syndromes</b> Russell-Silver syndrome Seckel syndrome Prader-Willi syndrome <b>Storage disorders</b> Glycogen storage disorder <b>Inborn errors of metabolism</b> Aminoacidopathies Recurrent hypoglycemia Organic acidemia

\*Failure to thrive (FTT) usually manifests by 8 weeks of age

## CLINICAL FEATURES

The clinical presentation of FTT depends on the age at onset, associated symptoms, severity of malnutrition and the degree of impairment of growth parameters. The correlation of deceleration of weight as compared to length/height and head circumference gives a possible etiological clue. Children with nutritional deficiency initially have poor weight velocity followed by slow deceleration of height velocity and then poor head growth as compared to children with normal variants where the velocity of growth will be normal.

Children with systemic illnesses causing FTT may manifest as early as 8 weeks of age depending upon age at onset of illness and have more severe weight deficit as compared to children with behavioral difficulties leading to poor feeding who may present late. Presence of associated symptoms like respiratory distress, cyanosis, recurrent diarrhea, vomiting, jaundice and food allergy is suggestive of an underlying illness. In children with FTT due to organic causes, presence of dysmorphic features, anomalies like cleft lip or palate, cyanosis, respiratory distress, cardiac murmurs, developmental delay and tone abnormalities should be evaluated. Some conditions such as food allergies, chronic renal insufficiencies and celiac disease can have subtle presentation and need careful evaluation of growth over multiple visits.

The assessment of severity of FTT is helpful for effective intervention. The severity of FTT can be assessed by various methods (**Table 3**). Gomez method based on child's weight as a percentage of median weight expected for age is a commonly used tool to classify severity of FTT. Wellcome method uses the child's height as percentage of expected median height for age and child's weight as a percentage of median weight for a child of his/her height. McLaren method assesses severity of malnutrition by using ratio of present weight to height as compared to median weight:height ratio for age. Besides anthropometric characteristics, children with FTT may have associated recurrent infections of respiratory, GI tracts, skin involvement in the form of dermatitis, impetigo, alopecia, associated loss of subcutaneous fat and muscle mass and features of vitamin deficiencies. Signs of neglect in the form of poor personal hygiene, uncut nails, diaper rash, dirty and soiled clothing and body louse may also be seen.

Features of abuse should be actively looked for. A child abuse is suspected if features suggestive of problems are seen in five or more organ systems, presence of five or more food allergies and absence of serious congenital anomalies or genetic defects. Presence of unexplained, unusual and multiple injury marks especially of different ages, suggests physical abuse.

## APPROACH TO DIAGNOSIS

A detailed history, thorough physical examination and careful observation of child parent interactions help in making accurate

diagnosis. Evaluation of FTT can be categorized based on the age at onset (**Table 4**).

## History

A careful dietary history is the foremost aspect of evaluation of a child with FTT. Diet assessment for meal content, meal timings, types of food, access to aerated drinks, etc., needs to be recorded. Consumption of a lot of fruit juices not only affects appetite but also does not provide enough calories. Dietary details can be obtained either based on a 3 day diet diary or 24 hours dietary recall. It is also very useful to actually observe the parent child interaction during a feeding session. Important cues like poor latching in breastfed baby, improper preparation of formula milk, gagging, vomiting, rumination, mother's response to baby's signals of satiety/hunger, feeding interactions, coercive feeding, autonomy struggle, distractibility and any stress can be observed. The quantity of feed can also be measured to assess for adequacy.

Presence of oromotor dysfunctions, swallowing difficulties, sensory based feeding problems, i.e., inability to appreciate texture of various food substances, causes poor feeding especially in early infancy. Congenital anomalies like cleft lip and palate, neuromuscular disorders causing hypotonia/hypertonia, organ system symptoms like recurrent or chronic diarrhea, vomiting, breathlessness, cyanosis, jaundice, seizures, etc., should be elicited. Contact with tuberculosis, HIV status, immunization

**Table 4** Etiology of failure to thrive

By age of onset	Likely cause
Prenatal period	Prematurity Intrauterine growth restriction (IUGR) Intrauterine infection (TORCH) Exposure to drugs/substance abuse/teratogens
Neonatal period	Breastfeeding problems Incorrect milk/formula preparation Inadequate number of feedings Poor feeding interactions, neglect Misread signals of satiety/hunger <i>Metabolic disorders:</i> Lethargy, poor feeding, seizures, dehydration, jaundice, respiratory distress, etc. <i>Chromosomal anomalies:</i> Dysmorphic features <i>Structural anomalies:</i> Cleft lip, cleft palate
3–6 months	Underfeeding (poverty, lack of knowledge) Milk protein allergy—cow's milk <i>Celiac disease:</i> On weaning to wheat containing diet Recurrent/chronic diarrhea, blood in stools, oily greasy stools, worms in stools <i>Oromotor dysfunction:</i> Poor swallowing <i>Cardiac diseases:</i> Poor feeding, suck-rest-suck, cyanosis, breathlessness <i>Gastroesophageal reflux disease:</i> Recurrent vomiting
7–12 months	Poor quality and inadequate quantity of complementary foods <i>Systemic illnesses:</i> Heart disease, liver dysfunction, repeated infections due to poor hygiene Feeding problems include difficulty to appreciate texture of various food, autonomy struggle, strict parenting approach, delayed introduction of solid food Oromotor dysfunction
> 12 months	Poor quality and inadequate quantity of complementary foods Coercive feeding, highly distractible child, distractible environment Autism and other behavioral problems Poverty, child neglect/abuse

**Table 3** Severity of failure to thrive (FTT)

Method	Mild FTT	Moderate FTT	Severe FTT
<i>Gomez classification</i> Present weight/median weight for age	75–90%	61–75%	< 60%
<i>Wellcome classification</i> Height/Median height for age Weight/Median weight for height	90–94% 80–89%	85–89% 70–80%	< 85% < 70%
<i>McLaren classification</i> (Present Weight: Height)/ (Median Weight: Height for age)	81–90%	70–80%	< 70%
<i>Classification based on height</i>	90–95%	85–89%	< 85%

history is useful to exclude associated infection as a cause. Family history of short stature, any significant illnesses and parental height need to be elicited to rule out genetic causes of short stature (**Table 5**).

### Physical Examination

Accurate measurement of the anthropometric parameters, weight, height/length, head circumference is essential for diagnosis of FTT. A meticulous plotting of these growth parameters on the reference chart is the cornerstone of accurate and timely diagnosis.

Assessment of weight for age, length for age and weight for length parameters not only helps in differentiating FTT versus constitutional or genetic causes of growth faltering, but these parameters also are used to assess severity of FTT and acute versus chronic malnutrition. In children with FTT, the weight for age is uniformly affected as also the weight velocity. In acute malnutrition weight for age is more affected as compared to chronic nutritional deprivation where length for age is affected to a similar extent as weight. Children with organic cause of FTT present earlier and have more severe weight deficit as compared to nonorganic causes

**Table 5** Clinical evaluation of failure to thrive (FTT)

<i>History</i>	<i>Interpretation</i>
<b>Diet</b>	
• Diet assessment	Quantification of total calorie intake
• Technique of milk/formula preparation	<i>Overdiluted milk:</i> Low calorie content <i>Overconcentrated milk:</i> Unpalatable
• Type of food—fruit juice, soda, aerated drinks, water, inadequate or inappropriate complementary foods	Poor calorie intake
<b>Feeding behavior</b>	
• Observed feeding session	Helps to understand behaviors like easy distractibility, proper supervision, feeding battles, parent child interactions, swallowing dysfunction
• Technique of feeding	Improper technique
• Intermittent snacks	Poor meal time eating, early satiety
<b>Medical history</b>	
• <i>Birth history:</i> Intrauterine growth retardation, prematurity, complications at birth	Catch-up growth may be incomplete in many babies
• <i>History of recurrent illness:</i> Otitis media, diarrhea, pneumonia	Inadequate catch-up growth opportunity in between illnesses
• Contact with tuberculosis, human immunodeficiency virus (HIV), recurrent infections	Tuberculosis, HIV infection, other immune deficiency states
• Stool pattern, worms in stool	Malabsorption syndrome
• Polyuria, polydipsia, FTT despite increased appetite	Renal tubular acidosis, diabetes insipidus, diabetes mellitus, hyperthyroidism
• Vomiting and reflux	Gastroesophageal reflux disease (GERD)
• <i>Past medical history:</i> Chronic anemia, asthma, renal disease, cardiac disease, liver disease	Pointers towards organic causes of FTT
• Injury marks, frequent accidents	Neglect, abuse
<b>Family history</b>	
• Parental height, sibling height	Shorter parental height and higher parity has been shown to have slow weight gain in infancy
• Any illnesses in family	Developmental delay, constitutional delay
• Discord/stressors in family	Child neglect
<b>Clinical examination</b>	<b>Interpretation</b>
<i>Anthropometry:</i> Accurate measure weight, height/length, head circumference and plot on reference growth chart	Severity of FTT
Recurrent diarrhea, anemia, poor growth, poor appetite	Celiac disease
Steatorrhea, chronic respiratory signs, bronchiectasis, salt wasting crisis, increased sweat chloride	Cystic fibrosis
Icterus, hepatomegaly, splenomegaly, pallor bleeding, ascites	Chronic liver disease
Breathlessness, with/without cyanosis, murmur	Congenital heart disease
Recurrent abdominal pain, bloody diarrhea	Milk protein allergy, inflammatory bowel disease (in older children)
Recurrent aspiration pneumonia, asthma mimic with/without vomiting	Gastroesophageal reflux disease
<i>Organ specific signs:</i> Neurological, immunological, renal, etc.	Organ specific illnesses

of FTT. Once it is ascertained that the child has FTT, it is essential to detect any features of dysmorphic/genetic syndrome, signs of any underlying organ system disease or infections and detailed evaluation for features of child abuse.

Signs of vitamin deficiencies and any danger signs should be looked for (**Fig. 1**). Presence of pallor, dry sparse hair, cracked skin, loss of subcutaneous fat, poor musculature, distension abdomen and features of sepsis are suggestive of severe FTT.

**Figure 1** An 8-week-old male child born at term with a birthweight of 1.7 kg, with severe failure to thrive (FTT) due to systemic illness—chronic liver disease, ichthyosis and sepsis. Present weight is 1.7 kg

Signs of organic causes of FTT like organomegaly, lymphadenopathy, anemia, cardiac signs like features of congestive failure, cyanosis, cardiac murmurs, pulmonary problems like respiratory distress, chronic respiratory failure, diarrhea, dehydration, and presence of recurrent unexplained injuries must be observed (**Table 5**).

Observing the parent child interactions in children with psychosocial cause of FTT is essential. Observe for eye to eye contact, response of the parent to the baby's cue of hunger or satiety. Aggression or anger while feeding on the part of parent has often caused rupture frenulum, poor feeding and feeding battles. Disinterest in feeding, anxiety also cause poor nutrient intake and FTT.

In a large number of cases, there may be no clinical features of FTT and hence serial growth monitoring is essential to diagnose these children early.

### Laboratory Evaluation

Routine laboratory testing not guided by history and physical examination has limited utility in evaluation of children with FTT. Hence laboratory investigations are recommended only in presence of clinical clues to get better yield. Complete blood counts, serum creatinine, blood urea nitrogen (BUN), electrolytes, blood sugar and urine analysis would be useful as initial screening tests. Tests for hypoproteinemia, hypoalbuminemia and calcium-phosphorus disturbances along with hepatic and renal function tests as well as stool examination for parasites and fat globules can be done in cases of severe FTT. Specific tests like antigliadin antibodies, tissue transglutaminase IgA for celiac disease, sweat chloride test in suspected cases of cystic fibrosis, venous blood gases for renal tubular disorders, metabolic screen for suspected metabolic disorders, karyotype for chromosomal disorders, etc., are done as and when indicated (**Table 6**).

**Table 6** Laboratory evaluation of failure to thrive

Tests	Interpretation
Complete blood counts	Anemia, infections
Urine analysis	Urinary tract infections
Stool examination for ova cyst, fat globules	Parasitic infestations, fat malabsorption
Total protein and albumin	Hypoproteinemia
Liver function tests: ALT, AST, PT, PTT, aPTT	Chronic liver disease
Tests for tuberculosis and congenital infections	Tuberculosis, congenital infection
Tests for HIV	HIV
Renal function tests: Serum creatinine	Chronic kidney injury
Serum electrolytes, venous blood gases	Renal tubular acidosis
Celiac screen	Celiac disease
Sweat test	Cystic fibrosis
Skeletal survey	Look for evidences of physical abuse; dysmorphic syndromes
Bone age	To differentiate genetic causes from nutritional causes: BA = CA (genetic) BA < CA (nutritional)
Thyroid function tests	Hypothyroidism/hyperthyroidism
Metabolic screen	Inborn errors of metabolism
Allergy testing	Specific food allergy
Karyotype	Chromosomal disease

**Abbreviations:** BA, bone age; CA, chronologic age; ALT, alanine aminotransferase; SGPT, serum glutamic pyruvic transaminase; AST, aspartate aminotransferase; SGOT, serum glutamic oxaloacetic transaminase; PT, prothrombin time; PTT, partial thromboplastin time; aPTT, activated partial thromboplastin time; HIV, human immunodeficiency virus; BA, bone age; CA, chronological age.

### MANAGEMENT

Failure to thrive especially in early infancy has long-term effect on stature and neurocognitive function. Prompt diagnosis and early intervention helps in preventing these irreversible deficits. The goals of treatment include:

- Improving nutritional status through provision of adequate nutrition
- Treating the underlying medical cause of FTT, if present
- Improving caregiver's ability to provide appropriate and adequate diet to the child through education, capability enhancement and psychosocial support
- Preventing a relapse of FTT through close follow-up and monitoring.

The management depends on the severity of FTT. In mild FTT, increase in nutrient intake can be achieved by making appropriate changes in diet content, feeding schedule and/or feeding environment. Continuing to provide home-based food with correction of faulty feeding practices and suitable modifications to improve calorie content are helpful. Feeding environment with minimal distractions helps in achieving better intake of food and less of *food battles*. Thus there is no need for any special diet or drugs in mild FTT. These children should be regularly monitored to document a catch-up in weight.

Moderate FTT needs a multidisciplinary team comprising of a pediatrician, dietician, child psychologist, developmental

specialist, social worker and a nurse practitioner for optimum management. Although these children can be managed in outpatient clinics, frequent follow-up and sometimes home visits may be needed. Diet modified to provide calorie-dense food, treatment of any underlying medical illnesses, improving psychosocial problems, changing feeding environment, feeding routine may help in treatment of these children. Failure to exhibit a catch-up growth is an indication for admission for dietary management under observation and evaluation of an underlying organic cause. Children with severe FTT need to be hospitalized so as to prevent further deterioration of nutritional status and to provide controlled refeeding under direct observation. Indications for hospitalization in a child with FTT include:

- Severe FTT
- Underlying medical problem requiring in-hospital care
- Failure to respond to several months of outpatient management
- Psychosocial circumstances that put the child at risk for harm
- Practicality of distance, transportation, or family psychosocial problems precluding outpatient management.

*For management of severe acute malnutrition in hospital setting please refer to the Section 23 on Nutritional Disorders.*

### Calorie Requirement

In children with FTT improving intake of calorie and other micronutrients and vitamins is important to achieve catch-up growth. High calorie diet should be provided at 150% of recommended daily calorie intake based on the expected weight and not the actual weight. Thus a 1-year-old child with FTT, who is expected to weigh 10 kg, will need 1,100 Cal/day. This can be achieved by gradually increasing food intake or by enrichment of food to increase calorie content.

Increasing food intake helps in catch-up growth in scenarios of insufficient availability of food such as poverty, nonavailability of food, lack of knowledge of adequate and appropriate food and food faddism.

Increasing calorie content of food can be achieved by fortifying food with carbohydrates and/or fat bearing in mind the calorie density so as not to cause an imbalance of ratio of calorie, protein, water and nutrients. Calorie content can be increased by providing concentrated formula milk, or by adding cereals, pureed food or cream, to milk.

Multivitamins as per recommended daily allowance must be added. It has been shown that addition of zinc helps reduce the energy cost of weight gain during catch-up growth.

As consumption of excess fluids decreases the appetite for solid food, intake of fruit juices should be avoided/restricted to 8–12 oz per day. The focus should instead be on addition of fresh fruits and vegetables. At meal times solids should be offered before liquids.

### Feeding Pattern

As far as possible a constant feeding schedule as per the age of the child should be followed. An infant will need to feed 8–12 times per day in the first 4 months as compared to 6–8 feeds per day in later infancy. Children more than 1 year of age should follow the pattern of *rule of 3*, i.e., 3 meals, 3 snacks and 3 choices. Grazing diet should be avoided and snacks should be timed at least 1 hour before meal time.

Feeding environment should be comfortable and relaxed with minimum distractions. Eating with other family members should be encouraged. Forced feeding, strict parenting approach, autonomy struggles lead to food battles and create unpleasantness

and should be avoided. Regular interaction between physician, dietician, nurse practitioner, and psychologist is essential for achieving a good catch-up growth.

### Treatment of Underlying Medical Illness

Organic cause of FTT should be treated with appropriate management. Pancreatic enzyme replacement in fat malabsorption, cystic fibrosis and other conditions with pancreatic insufficiency, gluten free diet in celiac disease, avoidance of allergic substances in food allergy, specific treatment for chronic liver disease, congenital heart disease, renal failure, renal tubular acidosis, and endocrine disturbances should be provided. Immunization as per national schedule should be administered. Any intercurrent illness should be treated promptly.

### Psychosocial Interventions

Interventions to improve parent-child interactions through group activities, empowerment through provision of knowledge, guidance and support are important aspects of management of FTT, both organic and nonorganic.

### Follow-up and Monitoring

Catch-up growth is achieved with appropriate nutritional, medical, behavioral and environmental interventions within 3 days to 2 weeks based on severity of FTT. Usually 6–9 months of catch-up growth is essential to restore weight for height. The restoration of normal height velocity takes longer as compared to weight recovery and hence close monitoring, continued nutritional intervention and ongoing care are essential. At each follow-up visit besides anthropometric assessment, developmental and behavioral monitoring should continue.

Not achieving a catch-up growth despite 2–3 months of adequate nutritional intervention is treatment failure and calls for hospitalization and detailed evaluation of organic causes of FTT.

### OUTCOME AND PROGNOSIS

Failure to thrive is a nutritional syndrome with long-term effects on stature, developmental and cognitive functions. Although the final height is dependent on parental height and genetic potential, the severity of FTT, age at onset of FTT and severity of associated underlying medical illness contribute to the final height outcome. Effect of FTT with onset in first 6 months of life is difficult to overcome and these children remain stunted despite adequate treatment. Various follow-up studies show a good catch-up for weight, though the stature remains affected in nearly 25–60% cases on long-term follow-up.

A systematic review of long-term outcome of children with FTT showed that these children remain shorter, lighter and score less on psychomotor developmental scales than their peers. It is nevertheless a challenge for physicians to identify children with FTT early, make an etiological diagnosis and initiate interventions as required to prevent long-term sequel related to stature, developmental and cognitive outcome.

More recently malnutrition and enteric infection in early infancy have been linked to risk factors for cardiovascular disease and type 2 diabetes mellitus in adulthood. Although the etiology remains unclear, both calorie deficit and infection-related inflammation are contributors to future cardiovascular and metabolic disease besides having effect on stature and neurocognitive development. Given the long-term implications on stature, neurocognitive development and adult diseases, prevention of FTT is an important aspect of child care.

### IN A NUTSHELL

1. Failure to thrive denotes inadequate growth especially in early childhood, due to lack of sufficient *usable* nutrition contributed by biological, environmental and psychosocial factors.
2. Accurate measurement of the anthropometric parameters and their meticulous plotting on the reference chart is the cornerstone of accurate and timely diagnosis.
3. Inadequate calorie intake is the most common cause of FTT. Organic and nonorganic causes of FTT may often coexist in the same child.
4. FTT has long-term implications on stature, neurocognitive development and vulnerability for adult-onset diseases. Hence prevention of FTT and early diagnosis are important aspects of child care.

## Chapter 19.7

# Overweight and Obesity

Rajesh Khadgawat, Aashima Dabas

Childhood obesity is a major public health problem of the modern world which has shown increasing trends globally in the recent years. The World Health Organization (WHO) defines childhood obesity as one of the most serious public health challenges of the 21st century, due to its rapidly increasing prevalence and tracking seen till adulthood. Out of the projected 1.5 billion overweight people in 2015, it is estimated that children will constitute around 10% and approximately 75% of these will be from developing countries. There has been a parallel rise of conditions like dyslipidemia, hypertension, abnormal glucose tolerance, and reduced health-related quality of life in pediatric age group which is attributed to increased prevalence of obesity in the population. India is fighting a dual problem; on one hand malnutrition is still widely prevalent while on other hand, childhood obesity is becoming frequent in urban locations particularly among children of higher socioeconomic status.

## EPIDEMIOLOGY

The prevalence of overweight/obesity is dramatically higher in the developed countries as compared to the developing world. However, in recent past, it has almost plateaued after introduction of obesity prevention and control programs at community level. On the contrary, obesity still remains a big challenge in developing countries. Cross-sectional studies across India have shown prevalence of overweight in 10–14% and obesity in 3–6% of pediatric population in the last few years. Obesity in Indian preschool age group has not been well studied but available data indicates rising prevalence.

Obesity can occur at any age, but the three most vulnerable periods for its development are prenatal period, age of 5–7 years and adolescence. More than 90% of the fetal fat deposition occurs in the last trimester of pregnancy. During early infancy (4–6 months), fat deposition accounts for 40–65% of total body weight gain. This burst of fat accumulation is followed by a gradual decline to a *lean state* by 5–6 years of age. This is followed by rapid gain in fat as well as muscle mass during adolescence under influence of sex steroids.

## DEFINITION

Obesity is excess accumulation of body fat. The definition of *excess* varies with the parameter used for measuring. Measurement of weight is the earliest parameter used for definition of obesity; weight more than 120% of expected was considered as excess for defining obesity in adults. One of the major drawbacks of using a weight-based criterion is its dependency on height. This led to use of weight corrected for height defined as *body mass index (BMI)*. The gold standard for fat measurement is hydrostatic/underwater weighing. Other parameters like waist circumference (WC), waist-hip ratio (WHR), total body fat, fat mass index have also been used, but BMI remains most widely accepted and used parameter for defining obesity in children.

## Body Mass Index

In relation to age, BMI progressively increases after birth to around 1 year, followed by decrease till the age of 6 years, and then increases through the remainder of the childhood and adolescence. The point of the lowest level of BMI around 6 years after which it starts increasing again is termed as *adiposity rebound*. Adiposity starting earlier than the time expected for obesity rebound is associated with increased risk of subsequent obesity. In children, there is no single cut-off of BMI for definition (as in adults) in view of rapid

changes in BMI during puberty. Age and gender specific BMI charts have been used by many countries for definition of obesity. Based on National Health and Nutrition Examination Survey (NHANES, USA) data, an expert committee recommended age and gender matched BMI greater than 95th centile as cut-off for *obesity* and that between 85th and 95th centiles as *overweight*. UK90 BMI charts are used in UK where obesity is defined as age and gender matched BMI greater than 95th centile. Recently BMI reference data for Indian children have been published (See Chapter 19.3).

The International Obesity Task Force (IOTF) has set age and gender specific cut-offs for defining *overweight* and *obesity* based on BMI data from children in six high and middle income countries. These charts have yielded gender specific cut-offs of BMI at six monthly age intervals. The IOTF data was pooled together from six countries (data collection period 1963–1993) and centile curves were drawn in such a way that they pass through the points of 25 kg/m<sup>2</sup> and 30 kg/m<sup>2</sup> (reflecting WHO recommended definitions of adult overweight and obese) at age 18. Although, the available reference data do not represent the world's population, these cut-offs are widely used all over the world for both clinical, research as well as epidemiological purposes. A major shortcoming of BMI is that it measures excess weight relative to height, and not excess body fat. Therefore, it cannot differentiate between muscular and fatty bodies.

Other methods of body fat estimation are summarized in Table 1.

## CLASSIFICATION

### Primary/Constitutional Obesity

This is by far the most common type of obesity seen in children and responsible for more than 95% cases. Its cause is primarily nutritional and it results from an imbalance between energy intake and energy expenditure. It is not explainable by known genetic or metabolic defects. However, with improved understanding of epigenetics, more cases of primary obesity can be explained by single gene disorders.

### Secondary Obesity

These are uncommon causes of obesity seen in practice.

- **Monogenic** Monogenic obesity is associated with a single gene mutation, insertion or deletion (e.g., a mutation in the leptin/melanocortin pathway, resulting in severe obesity). Certain genes near which variants have been discovered for children with obesity include fat mass and obesity associated gene (*FTO*), melanocortin-4 receptor (*MC4R*) and others such as *ADCY5*, *ETV5*, *KCTD15*, *GNPDA2* and *TMEM18* loci.
- **Polygenic** Polygenic obesity results from a complex interaction of multiple genetic, social, environmental, and behavioral influences, e.g., single nucleotide polymorphisms of the *PSMA6* and *PSMA3* proteosomal genes affecting gene expression.
- **Syndromic** It involves concurrent mental retardation, dysmorphism, and/or organ-specific developmental abnormalities, e.g., Prader-Willi syndrome (PWS), Down syndrome, Albright hereditary osteodystrophy, Bardet-Biedl syndrome, fragile X syndrome, Cohen syndrome and Carpenter syndrome. PWS results from deletion of paternal deoxyribonucleic acid (DNA) in the region of long arm of chromosome 15 (q11–13) and manifests as neonatal hypotonia, delayed milestones, hyperphagia, obesity, short stature, delayed puberty, epilepsy and mild to moderate degree of cognitive impairment. Bardet-Biedl syndrome presents with obesity, hyperphagia, retinitis pigmentosa, polydactyly, hypogonadism and mental subnormality.
- **Endocrine** These include Cushing syndrome, pseudohypoparathyroidism and hypothyroidism and are discussed in separate chapters (Section 44).
- **Hypothalamic** This is an extreme form of obesity resulting from functional or anatomical damage to hypothalamus.

**Table 1** Available methods of body fat/body composition assessment

Method	Instrument	Available cut-offs	Role/feasibility	Comments
Hydrodensitometry (under water weighting)	Complex large equipment setting	No	Based on Archimedes' principle of buoyancy, expensive, used only in research setting	Often considered as "Gold Standard", difficult to carry out in pediatric population
Air displacement plethysmography (ADP)	Relatively smaller but costly equipment	No	Air is used in place of water, used in research setting	Useful for infants also, quick measurement
Body mass index (BMI)	Weighing machine and stadiometer	Yes	Simple, inexpensive, applicable to field studies	Does not differentiate body fat and muscle mass
Waist circumference/ Waist hip ratio (WC:WHR)	Estimate of abdominal fat, measured midway between the lateral lower rib margin and the uppermost lateral border of iliac crest, measured by measuring tape	No	Simple, reproducible, measures subcutaneous fat, applicable to field studies	Lack of valid cut-offs in children, poor correlation to estimation of visceral fat
Skin fold thickness	Old research tool, measured by caliper at different sites (biceps, triceps, subscapular, suprailiac and thigh) and an equation is used for calculation of total body fat mass	No	Low cost instrument, applicable for field studies, widely used for estimation of total body fat	Expertise needed, lack of validity, may underestimate body fat in obese, does not measure visceral fat, poor reproducibility
Ultrasound	Portable ultrasound machine	No	Portable, noninvasive, measures subcutaneous fat	Underestimates body fat in obese, interobserver variability, poor reproducibility, not cost-effective
Bioelectrical impedance analysis	Based on ability of different tissues of the body to give different resistance to flowing current in the body. This resistance is measured for total body water and fat free mass content, from which, total body fat can be calculated. Analyzer: 2/4/8 electrode	No	Portable, simple, convenient and inexpensive method for assessing adiposity	Variability with body hydration, limited availability and validity
Dual energy X-ray absorptiometry (DEXA)	Provides precise body composition analysis and is able to detect small changes in body composition in both, adults and children, DEXA machine	Yes	Often considered as gold standard, scan time is more, difficult for epidemiological studies	Requires standardization, high costs, equipment not widely available

Initially, it was described in patients with hypothalamic tumor but later, was also reported in other diseases (**Table 2**). It results from functional impairment of the hypothalamic regulatory centers especially ventromedial nucleus (VMN), which is a key regulator of appetite and weight in the human body. Markedly increased and uncontrollable urge to eat is one of the important features of this condition along with decreased physical activity. Other disturbances like autonomic imbalance, growth hormone (GH) or gonadotropins or thyroid-stimulating hormone (TSH) deficiency have also been reported. These patients also exhibit hypomobility of joints, insomnia, inappropriate behavior and emotional blunting. Obesity in these children is associated with other endocrine dysfunctions such as hyperleptinemia and hyperinsulinemia. Hyperinsulinemia in hypothalamic obesity results from altered neural regulation of the  $\beta$ -cells of pancreas, unlike peripheral insulin resistance seen in children with simple obesity. There is no single effective treatment in such cases as hyperphagia is difficult to control; both drugs and surgery have shown limited results.

- **Drugs** Certain drugs like antiepileptics, steroids, estrogen can also result in substantial weight gain.

## PATHOPHYSIOLOGY

Unlike earlier belief, the adipocytes are not mere passive energy storage sites. The preadipocytes are capable of functioning as macrophages and producing various inflammatory cytokines like interleukin-6 (IL-6), tumor necrosis factor alpha (TNF $\alpha$ ), and adiponectin. The adipocytes also produce adipokines which regulate concentrations

of C-reactive protein and interleukin-10 (IL-10). Other inflammatory molecules produced by adipocytes include leptons, lipoprotein lipase, angiotensin, atrial natriuretic peptide, free fatty acids, insulin-like growth factors, etc. These molecules are responsible for insulin resistance and endothelial dysfunction as seen in obesity.

Appetite and satiety control is a complex interplay between leptin (hormone secreted by adipose tissue) and ghrelin (hormone secreted by gastric fundus) with support from other cytokine and hormones. During fasting, low leptin levels increase appetite and decrease energy expenditure by stimulating neuropeptide-Y synthesis and inhibiting sympathetic and other catabolic pathways. Conversely, during feeding and weight gain, increased leptin levels decrease appetite and increase energy expenditure through release of melanocortin and corticotropin-releasing hormone (CRH). The integrated output of these molecules leads to the behavioral and neurohumoral outputs to maintain body weight and adiposity. Both leptin and insulin enter the brain and act as inhibitors of food intake, activate thermogenesis and inhibit the production of proopiomelanocortin (POMC) which has catabolic properties. **Table 3** summarizes the role of hormones and other mediators in pathophysiology of fat regulation.

## Risk Factors Associated with Obesity

The factors influencing obesity start with in utero fetal programming and continue into adulthood with lifestyle/behavioral factors. The various sociodemographic risk factors, associated with obesity in children and adolescence are summarized in **Table 4**.

**Table 2** Causes of hypothalamic obesity in children and adolescents

• <i>Tumors:</i> Primary as well as secondary tumors involving hypothalamus—craniopharyngioma the most common cause
• <i>Inflammatory lesions of hypothalamus:</i> Tuberculosis, sarcoidosis, arachnoiditis, histiocytosis X, viral encephalitis
• <i>Head trauma or neurosurgery</i> in the vicinity of hypothalamus
• <i>Cranial radiotherapy</i>
• <i>Single gene mutations:</i> Leptin, leptin receptor, CART, POMC, prohormone convertase-1, MC4R, BDNF (TrkB), single-minded 1 (SIM-1)
• <i>Genetic syndromes:</i> Prader-Willi syndrome, Bardet-Biedl syndrome, Rapid-onset obesity with hypoventilation, hypothalamic dysfunction, and autonomic dysregulation (ROHHAD) syndrome
• <i>Psychotropic drugs:</i> Antipsychotic and antidepressants drugs

**Table 3** Various cytokines/adipokines and hormones implicated in pathogenesis of obesity

Hormone/ cytokine	Site of production/ secretion	Physiological effects/function
Leptin (satiety hormone)	Adipocytes	Crosses the blood-brain barrier and inhibits energy intake at the level of hypothalamus, thus regulates the amount of fat stored in the body by modulating food intake and energy expenditure
Ghrelin (hunger hormone)	Stomach	Regulates energy balance, appetite and promotes fat deposition by decreasing usage of fat for metabolism
Adiponectin	Adipose tissue	Insulin-sensitizing, anti-inflammatory and antiapoptotic actions, also increases energy expenditure and cause weight loss. Levels are inversely correlated with body fat percentage in adults
Tumor necrosis factor (TNF)	Macrophages and other immune cells, also by adipose tissue	Multifunctional cytokine implicated in inflammation, apoptosis and cell survival as well as induction of insulin resistance Major link between insulin resistance and obesity
Obestatin	Stomach and small intestine	Postulated to influence long-term weight control
Orexins A and B	Hypothalamus	Primarily involved in the stimulation of food intake
Resistin	Macrophages	Induces insulin resistance
Interleukin-6 (IL-6)	Macrophages and other immune cells	Proinflammatory cytokine, link between obesity and insulin resistance
Apelin, Visfatin, Vaspin	Adipose tissue	Not clear role, probably link between obesity and associated complications like insulin resistance and atherosclerosis

Abbreviation: POMC, proopiomelanocortin.

## COMPLICATIONS AND COMORBIDITIES

Obesity in childhood and adolescence is associated two types of risk/complications: (1) those manifesting during childhood and adolescence; (2) those whose risk of occurrence during adulthood

**Table 4** Risk factors/etiology of childhood obesity

Risk factor	Details	Comments
Prenatal factors	Growth retardation (IUGR), maternal pre-pregnancy overweight	Postulation of Barker's hypothesis on fetal origin of adult diseases
Early feeding practices	Lack of breastfeeding, increased formula consumption during early infancy, complementary feeding before 4 months	Breastmilk contains bioactive factors which inhibit adipocyte differentiation. Preterm infants fed on human milk have lower leptin levels in adolescence than formula-fed infants
Dietary	Increased junk food consumption, sweetened beverages, less fiber in diet	
Lifestyle	Increased screen time, lack of physical activities at home and school, shorter and irregular sleep duration	Electronic media exhausts the available play time. It is frequently associated with unhealthy snacking
Demographic	Parental overweight, low socioeconomic status and low parental education	Obesity higher in low socioeconomic class as lower parental education and food scarcity encourages habitual energy intake higher than energy expenditure with issues of healthy and nutritious food procurement
Medications/toxins	Drugs like antipsychotics (olanzapine, risperidone, antiepileptics and glucocorticoids. Toxins like endocrine disrupting chemicals (EDC) and bisphenol-A	Compounds like Bisphenol-A are used in packaging of common food stuffs like disposable plastics, cans and plastic packaging

Abbreviation: IUGR, intrauterine growth retardation.

is increased, these are summarized in **Table 5**. In addition, a constellation of these metabolic risk factors are increasingly being recognized among overweight and obese children known as *metabolic syndrome*. **Table 6** defines metabolic syndrome in children as per the classification by International Diabetic Federation (IDF).

## Long-Term Risk Associated with Childhood Obesity

Obese children and adolescents are more likely to become obese adults, and are therefore at higher risk of chronic noncommunicable diseases including hypertension, cardiovascular disease, dyslipidemia, insulin resistance and type 2 diabetes. The factors associated with persistence of childhood and adolescent obesity into adulthood obesity are severity of obesity, early age of onset of obesity and history of obesity in parents.

## EVALUATION

The main aims in evaluating a child who presents with obesity is to first ascertain the cause of obesity—whether primary or secondary and subsequently, assessment of obesity associated comorbidities and risk factors.

**Table 5** Comorbidities linked with obesity in children and adolescents

<i>System</i>	<i>Comorbidity/disease risk in childhood</i>	<i>Comorbidity/disease risk in adulthood</i>
Metabolic	Insulin resistance, dyslipidemia, impaired glucose tolerance, metabolic syndrome	Metabolic syndrome, type 2 diabetes
Cardiovascular	Hypertension, increased vascular stiffness	Atherosclerosis, left ventricular hypertrophy, diastolic dysfunction
Respiratory	Sleep abnormalities, asthma, obstructive sleep apnea syndrome (OSAS)	(same as during childhood)
Musculoskeletal	Slipped capital femoral epiphysis, tibia vara	Osteopenia
Gastrointestinal	Gastroesophageal reflux disease, nonalcoholic fatty liver	Nonalcoholic fatty liver, cholelithiasis, hernia
Endocrine	Early puberty in girls, hyperandrogenism and polycystic ovarian syndrome in girls	Type 2 diabetes
Psychosocial	Low self-esteem, depression, anxiety, social isolation	(same as during childhood)
Dermatological	Striae distensae, cellulitis, intertrigo, acanthosis nigricans, intertrigo, carbuncles, acrochordon (skin tags)	(same as during childhood)
Miscellaneous	Subclinical inflammation (elevated acute phase reactants), proteinuria, pseudotumor cerebri, meralgia paresthetica	(same as during childhood)

## History

A detailed clinical evaluation is mandatory in all children presenting with overweight/obesity; this may give important information regarding diagnosis and management, especially diagnosis of secondary obesity. Apart from general history taking in all subjects, following points should also be elucidated:

- History of maternal gestational diabetes or any other complication of pregnancy like gestational hypertension, intrauterine growth restriction (IUGR)
- Birthweight

- Weight gain during infancy, toddler and adolescent age groups
- Detailed history of sleep pattern including daytime somnolence
- Family history of obesity, diabetes in grandparents, parents and siblings, history of premature coronary artery disease (CAD)—clinically evident CAD below 55 years in men and below 65 years in women
- History of medications/supplements by the child—especially about use of steroids or psychotropic medications
- History of use of nutritional supplements for weight loss or height gain
- Developmental assessment—age of attainment of milestones, current school performance, any developmental disabilities (more likely to be affected in syndromic or endocrine types of obesity)
- Menstrual history in girls—age of menarche, menstrual irregularities.

## Examination

Apart from routine general and systemic physical examination, following should be recorded in all subjects with overweight and obesity:

- Anthropometric measurement—height, weight, waist and hip circumferences
- Blood pressure
- Signs of insulin resistance—acanthosis nigricans and skin tags
- Signs of hyperandrogenism (girls)—acne, hirsutism and increased hair fall
- Any dysmorphic feature/stigmata which may suggest secondary cause of obesity
- Pubertal status
- Psychiatric evaluation is very important and should be done in all children where any psychological maladjustment or disorder is suspected. It should be done only by professionals who have experience in dealing with psychological problems in children.

## Investigations

It is crucial to differentiate between primary and secondary obesity to plan subsequent work-up and management for the child. Children with primary obesity have normal or slightly accelerated growth and their bone age corresponds to age and height. However, those with secondary obesity generally have stigmata of underlying pathological process in case of genetic/endocrine causes such as dysmorphism, skin manifestations, etc. They are short and have delayed bone age. The distribution of fat is predominantly central in these children. Children with secondary causes may also have developmental delay/intellectual impairment and deviant sexual maturity (retarded/accelerated).

**Table 6** Definition of metabolic syndrome in children as per International Diabetic Federation (IDF)

<i>Age group (years)</i>	<i>Waist circumference (WC)</i>	<i>Serum triglyceride</i>	<i>Serum HDL-cholesterol</i>	<i>Blood pressure</i>	<i>Fasting blood sugar</i>
6–< 10	> 90th centile <sup>#</sup>	Metabolic syndrome cannot be diagnosed, but further measurements should be made if there is a family history of metabolic syndrome, type 2 diabetes (T2DM), dyslipidemia, cardiovascular disease, hypertension and/or obesity			
≥ 10–< 16	> 90th centile <sup>#</sup> or adult cut-off if lower	≥ 150 mg/dL	< 40 mg/dL	Systolic > 130 mm Hg or diastolic > 85 mm Hg <sup>#</sup>	≥ 100 mg/dL or known T2DM
≥ 16	WC ≥ 94 cm for men and ≥ 80 cm for women plus any two of the next four factors	≥ 150 mg/dL	< 40 mg/dL for men < 50 mg/dL for women	Systolic BP ≥ 130 or diastolic BP ≥ 85 mm Hg, or treatment of previously diagnosed hypertension	≥ 100 mg/dL or known T2DM

\*Age specific cut-offs for defining hypertension in Indian children

Abbreviation: HDL, high density lipoprotein

<sup>#</sup>National High Blood Pressure Education Program recommends blood pressure cut-off points of > 90th or > 95th percentile adjusted for height, age, and gender

**Table 7** Blood investigations required in evaluation of obesity

Investigations routinely required in evaluation of obesity	Investigations required only if clinical examinations suggest
<ul style="list-style-type: none"> <li>Complete blood count and blood film</li> <li>Liver and renal function tests including electrolytes</li> <li>Fasting lipid profile</li> <li>Oral glucose tolerance test—with 1.75 g glucose/kg body weight with maximum of 75 g; samples at 0 and 120 minutes</li> </ul>	<ul style="list-style-type: none"> <li>Tests of thyroid functions</li> <li>Tests of cortisol axis—overnight dexamethasone suppression test</li> <li>Tests of gonadal axis—serum LH/FSH/testosterone</li> <li>X-rays hand for bone age assessment</li> <li>Tests of growth hormone axis</li> <li>Serum vitamin D/parathyroid hormone—in subjects with skeletal symptoms</li> <li>Serum insulin/C-peptide—only in research settings</li> <li>Glycosylated hemoglobin (HbA1c)—no proven usefulness in children</li> </ul>

Abbreviations: LH, luteinizing hormone; FSH, follicle-stimulating hormone.

Basic and limited laboratory investigations are advisable in obese and overweight children to assess for associated metabolic abnormalities (**Table 7**). When secondary obesity is suspected, a detailed work-up and opinion of concerned specialist may be required.

## PREVENTION

Prevention of obesity begins with maternal health promotion activities before delivery of the child to prevent fetal growth restriction and ensure smooth antenatal course. Primary prevention of obesity is targeted at all levels, i.e., family, school, health professionals, government, industry and media. The *Global Strategy on Diet, Physical Activity and Health (DPAS)* was developed by the WHO in 2004. The four main objectives were:

1. To encourage the implementation of public health action and preventative intervention to reduce the risk factors resulting from unhealthy diet and physical inactivity.
2. To increase recognition of the implications of unhealthy diet and inadequate physical activity levels and knowledge of preventative measures.
3. To promote policies and action plans at all levels to address diet and physical activity behaviors.
4. To encourage monitoring, evaluation and further research.

The preventive strategies at individual level include changes in diet, lifestyle and physical activity as well as behavior.

## Diet

Health promotion activities should begin in early infancy reinforcing exclusive breastfeeding, timely complementary feeding and healthy feeding practices. As per dietary recommendations by American Academy of Pediatrics (AAP), no fat restriction should be done for infants younger than 2 years. For children older than 2 years, fat should contribute 20–30% of total calories. The fiber content in the diet should be approximately  $\text{age} + 5$  in grams. Feeding modifications suggested are:

- A variety of food products which are nutrient-rich and less energy dense should be included in the diet. The *traffic-light* diet approach should be emphasized—*Green (go)* for foods to be consumed in unlimited quantities like fruits and vegetables; *yellow foods (caution)* which have average nutritional value like grains and lean meat and ‘red foods (stop)’ for less nutrient, high energy density like sweetened and fried foods.
- The childhood feeding patterns should be facilitatory instead of adopting a coercive attitude.

- Proper guidance on age appropriate portions and energy density of foods should be emphasized.
- Skipping breakfast, frequent snacking and eating out should be avoided.

## Lifestyle/Physical Activity

The AAP recommends no television viewing for less than 2-years-old and the advised screen time (inclusive of television, computer and internet) should not exceed more than 1–2 hours per day for older children. Younger children and toddlers should have daily half to one hour of outdoor play. Older children should have moderate to vigorous exercise for 60 minutes daily of which 30 minutes should be during school time. Also, most of daily physical activity should be aerobic; however, vigorous activities which strengthen muscle and bone should also be included at least three times a week. Various studies have demonstrated that both aerobic and resistance type of exercise alone (without weight loss or calorie restriction) resulted in significant improvement in insulin sensitivity, suggesting that exercise alone is an effective therapeutic strategy for reducing insulin resistance in overweight and obese children and adolescence. In addition other activities like dance and sports are other attractive options which may be offered to a child. Sleep should be sufficient and timings should be regular. A preschooler should also have regular bedtime rules.

## Behavior

Parental motivation, commitment and simulation of healthy lifestyle are necessary. Older children should be educated and made responsible for their nutrition and exercise pattern. Facilitatory techniques include no stacking of unhealthy foods in house, setting realistic goals for exercise, positive reinforcement on successful diet change or exercise and timely monitoring.

## MANAGEMENT

The clinician should focus on child and develop a family-oriented approach with active involvement of parents. A multidisciplinary approach with a team including a pediatrician, dietician, psychologist and physical instructor is ideal. A need for a continuous life-long support is now more widely recognized due to the increasing knowledge of inherited susceptibility for developing obesity.

## Nonpharmacologic

The goals should be realistic, age-oriented and severe energy deprivation is avoided. Thus instead of a *set point*, a *settling point* for bodyweight is recommended. The weight is maintained fairly constant for long periods of time; and responsible behaviors for controlling energy intake and energy expenditure are developed influenced by environmental and cognitive stimuli. An overview of the dietary interventions is tabulated in **Table 8**.

Dietary management should be advised by qualified nutritionist or dietician in consultation with treating physician and parents. The ideal role of parents during weight-reducing period is supervision (of both physical activity and diet restriction) and inspiration for strict follow-up of advised measures.

The physical activity prescribed should be safe, developmentally appropriate, interesting and practical. It should involve the other family members too, to keep it sustainable and to improve compliance.

## Pharmacologic

Antiobesity drugs which are approved for use in adults are still being evaluated in children for their long-term safety and effect on growth. There have been instances where drugs which were approved earlier but withdrawn later due to potential side effects and safety issues (e.g., fenfluramine, sibutramine and rimonabant).

**Table 8** Dietary therapy for childhood overweight and obesity

Parameter	Age group	Weight monitoring	Recommendation
Overweight	Irrespective	Only monitoring, no targets set	Balanced diet (Traffic signal approach). Vitamin and minerals and average 1.5 liter water intake
Obese	Toddlers	Loss 0.5 kg/month	Carbohydrate as 45–65% of total calories, protein 10–20% and fat as 30–40% (< 8% as saturated)
	4–11 years	Loss 0.5 kg/month	Carbohydrate should constitute 45–65% of total calories, protein 10–30% in older children, and fat as 30–35% (< 8% as saturated)
	> 11 years	Loss 1.0 kg/week	Carbohydrate should constitute 45–65% of total calories, protein 10–30% in older children, and fat as 30–35% (< 8% as saturated)

The meta-analysis of available data for improvement in BMI with the use of these drugs in pediatric population is not more than 0.5–0.7 kg/m<sup>2</sup>, which is less than that reported by behavioral intervention trials.

The Expert Committee on Prevention and Pediatric Obesity (Endocrine Society Clinical Practice Guidelines) recommends the use of drugs for childhood obesity on individualized assessment after an adequate multidisciplinary conservative trial (generally for 6 months) has failed. Pharmacotherapy has been prescribed in children above 16 years of age who suffer from obesity-related complications. The only drug which has been approved by US Food and Drug Administration (FDA) is orlistat, and that too for use in 12–16 years old adolescents with obesity. No antiobesity drug is safe in younger than 12 years age.

### Surgical

The bariatric surgical procedures have shown good success with long-term safety in adults. These procedures can be malabsorptive, restrictive, or a combination of both. The two commonly used procedures are laparoscopic adjustable gastric banding (LAGB) and Roux-en-Y gastric bypass (RYGB). LAGB is a restrictive procedure where an adjustable plastic band is placed over stomach to divide it into two portions, proximal small pouch and distal large segment, thereby limiting amount of food to be ingested. RYGB is a combination procedure which restricts food intake as well as decreases nutrient absorption. Another procedure which is becoming popular nowadays is sleeve gastrectomy, which involves creating a tubular stomach through resection of the greater curve of the stomach. A J shaped tubular stomach is left with very limited capacity. This restrictive procedure also reduces appetite markedly. The use of surgical procedures in pediatric population is limited from case reports to very small case series only. The major concerns about these procedures in pediatric age group are ethical issues of consent from an adolescent for a nonreversible surgical procedure, absence of data on long-term safety and the effect of these procedures on growth, and development and fertility in case of girls. They may be offered to adolescents who have completed puberty (at least Tanner stage 4 or 5) with failed attempts to reduce weight by conservative methods with or without a trial of pharmacotherapy for at least 6 months and have:

- BMI more than 50 kg/m<sup>2</sup> in the absence of any comorbidity
- BMI more than 40 kg/m<sup>2</sup> and comorbidities like type 2 diabetes, obstructive sleep apnea or pseudotumor cerebri.

Although advancements in surgical techniques have made these surgeries simple with minimal complications, they should be carried out by only by experienced surgeons along with a trained team of supportive staff. A critical issue to be considered before opting for surgery is the child's and the family's motivation to adhere to advised nutritional and lifestyle related guidelines after surgery and commitment for long-term follow-up.

To summarize, obesity is an emerging chronic disease which has gained impetus since last decade or so. Childhood obesity should be treated as a serious medical illness as it has deleterious

long-term effects till adulthood. It needs to be recognized early and timely action should be instituted to prevent development of associated complications. Healthy diet and healthy lifestyle are the keys to prevent obesity and should be instituted from early childhood to be most beneficial.

### IN A NUTSHELL

1. Obesity can be either primary (constitutional) or secondary.
2. BMI is the most practical and widely used method for defining obesity in children and adolescents.
3. Age and gender based IOTF cut-off points should be used for diagnosis of obesity.
4. Asians are prone to central obesity than whites, and thus have higher risk for cardiovascular disease at lower levels of adiposity.
5. Dyslipidemia is common in overweight and obese children. Hypertriglyceridemia and low high density lipoprotein (HDL)-cholesterol levels are the most common derangement.
6. Metabolic syndrome in children (as defined by IDF) is based on raised waist circumference with any two of the following: hypertriglyceridemia, hypertension, fasting hyperglycemia or low HDL-cholesterol.
7. Evaluation of obesity includes careful history and examination to exclude secondary causes of obesity. Hormonal work-up should not be done unless clinically indicated.
8. The mainstay of therapy is conservative management which includes dietary, physical and behavioral modifications. Drugs have very limited role to play since none except orlistat are approved for use in this age group.

## Chapter 19.8

# Abnormalities of Stature

Senthil Senniappan, Leena Patel

## SHORT STATURE

### Definition

The definition of short stature requires interpreting the height of an individual in comparison to age and gender matched peers as well as the genetic potential based on parent's heights. The simplest way to do this in clinical practice is by plotting the child's and parent's heights on growth charts derived from local reference standards. Thus, an arbitrary definition of short stature is a height less than 2 standard deviations (SD) below the mean for age and gender at a single point, irrespective of a child's growth rate and/or ethnic origin. However, this definition is not absolute.

Short stature at a particular age does not necessarily imply that the individual has always been short nor does it predict short stature in the future and as an adult. Thus the following must be taken into consideration when determining whether an individual has short stature: previous stature, gender, stage of pubertal development, parents' heights, ethnic background and the growth performance of the reference population. A child can be considered to be short if height is below  $-2$  SD, there is a significant discrepancy between the child's height centile and mid-parental height centile, and the child's height trajectory has crossed two lower centile lines. Although a normal statured individual may have a negative psychological perception of being short, this is not within the remit of this chapter.

Normal growth through childhood, adolescence and until full pubertal maturation is well characterized. Therefore any deviation from this pattern in an individual is a sensitive indicator of active pathology until proven otherwise. Deviation downwards with declining centile positions means that the individual is shorter compared to their previous height. This is described as growth failure or faltering growth and reflects suboptimal height velocity (Fig. 1). It can occur in an individual who was previously of normal, short or tall stature, and requires careful evaluation.

### Epidemiology

Since height in any population follows a normal distribution, only 2.3% of healthy children are expected to have height measurement 2 SD below the mean for the population. Therefore, the further below this cut-off that an individual's height is, the greater is the likelihood that there is a pathological explanation for the short stature.

### Etiology

For the Indian subcontinent, the conditions associated with short stature and commonly encountered by general pediatricians include:

- Chronic undernutrition with deficiencies of energy, macronutrients (calcium) and micronutrients (vitamin D, iron)
- Chronic infections and infestations such as recurrent malaria, tuberculosis, human immunodeficiency virus (HIV), giardiasis, and intestinal worm infestations
- Chronic systemic conditions such as chronic renal failure, significant congenital defects (acyanotic defects associated with heart failure or cyanotic defects) and chronic hemolytic anemia.

In contrast, patients presenting to tertiary specialists are more likely to have normal variant short stature (constitutional delay in growth and puberty and familial short stature), endocrine causes (primary hypothyroidism and growth hormone deficiency) and syndromes such as Turner syndrome. Celiac disease and inflammatory bowel disease are increasingly being identified within the differential diagnosis owing to increased awareness and availability of diagnostic facilities.

### Pathogenesis/Pathophysiology

Growth impairment is a consequence of a pathology affecting any of the basic requirements for normal growth viz.: (1) hormones, (2) nutrition, (3) cell structure and function, (4) physical health and (5) psychosocial health (Table 1).

After a period of impaired growth, there is potential for catch-up growth if the underlying growth inhibiting condition is treated or modified. Catch-up is seen as accelerated linear growth and normalization of height towards the child's original trajectory. The extent of catch-up and whether normal adult height will be attained is influenced by the nature and severity of the underlying

**Figure 1** Growth chart to illustrate different patterns of linear growth. Mother's height is 146 cm and is plotted at 160 cm on a boy's chart ( $146 + 14$  cm). Father's height is 155 cm. Thus the mid-parental height (MPH) is 157.5 cm and the target range is 147.5–167.5 cm ( $MPH \pm 10$  cm)

Child A has familial short stature: He is short but his initial height is within parental target range. Follow-up measurements show that the height trajectory remains below but parallel to the 3rd centile and this suggests normal height velocity. The family can be reassured that this is familial normal variant short stature and no investigations or intervention are required.

Child B also has familial short stature. However follow-up measurements show the height trajectory deviating further away from the 3rd centile, characteristic of growth faltering. The latter suggests underlying pathology and needs to be investigated. The child also requires more frequent growth monitoring.

Child C is relatively tall for these parents but his initial height is still within parental target. Although his subsequent measurements remain within the parental target range as well as within the normal range for the population, there is a decline in the height trajectory similar to Child B. This child also has growth faltering and requires investigations for underlying pathology.

**Table 1** Basic requirements for normal growth and corresponding causes of growth impairment

Basic requirements for normal growth	Causes of growth impairment
Normal endocrine function The key hormones which regulate growth are growth hormone (GH) and sex steroids. Other hormones required for normal growth are thyroid, insulin, leptin, vitamin D and glucocorticoids	Defects in hormone secretion and action
Adequate nutrition	Undernutrition
Normal cells, cartilage and bones	Defects which impair structure and function
Physical health	Physical illness
Psychosocial health	Psychosocial deprivation

disease, age at onset and at diagnosis, pubertal timing, treatments and their success.

## Differential Diagnoses

### Normal Variant Short Stature

In a child with good general health and nutritional status, the most common causes of short stature are familial short stature (FSS) (**Fig. 1**), constitutional delay in growth and puberty (CDGP) (**Fig. 2**) or a combination of these two diagnoses. Birthweight, birth length, height velocity and body proportions are normal in both these conditions. Family stature, family history and normal height velocity helps to clinically differentiate these from growth hormone deficiency (GHD). Individuals with FSS have no delay in bone age, normal pubertal timing and will be short adults in keeping with a familial tendency. Those with CDGP may have a history of delayed puberty in parents. They have delayed bone age and delayed onset of puberty. Although they appear relatively short during childhood compared to parental target, their adult height will be on a higher centile position as compared to their childhood height centile and within their parental target (**Fig. 2**). Sometimes FSS and CDGP may coexist in a child. These children present at a younger age with concerns about short stature and will attain short adult height owing to the familial tendency.

### Chronic Undernutrition

Undernutrition is an important cause of short stature in resource-limited settings. It can also be associated with delayed puberty which further exaggerates the short stature. Undernutrition leads to low weight for height as well as low weight for age and gender. Although the most common deficiency is in energy, lack of other macronutrients (calcium) and micronutrients (vitamin D, iron and zinc) also needs to be considered. The cause of these deficiencies includes inadequate intake (poverty and feeding difficulties), unmet increased requirements (chronic inflammation) or excessive losses (malabsorption).

Adaptive mechanisms in chronic undernutrition are aimed to conserve energy and provide alternative sources of energy for body functions that are critical for survival. In such a state, substrate is diverted away from processes that are not a priority, such as growth, pubertal development and reproduction. Growth suppression is associated with relative GH resistance as indicated by normal or high spontaneous and stimulated serum GH in relation to low insulin-like growth factor 1 (IGF-1) and low IGF binding protein-3 (IGFBP-3) levels. Both IGF-1 and IGFBP-3 levels correlate with measures of nutritional status. Delayed puberty in

Growth chart for Indian children  
height-age-percentiles  
boys (5–18 years)

**Figure 2:** Growth chart to illustrate the pattern of growth in constitutional delay. At age 9.5 years, this boy is short for his parents (height below parental target range) and also for the population. His bone age is 7.5 years and thus delayed by 2 years compared to the calendar age. His subsequent growth measurements until age 14.2 years suggest normal height velocity for a prepubertal boy. Thereafter he has a pubertal growth spurt and his height at age 17 years is within the parental target as well as the normal range for the population. Note more frequent growth monitoring during the teenage years when the young person is prone to be psychologically affected about their physical appearance. That adult height attained will be on a higher centile compared to that in childhood can provide reassurance  
Source: Agarwal DK, Agarwal KN, Upadhyay SK, et al. Physical and sexual growth pattern of affluent Indian children from 5 years to 18 years of age. Indian Pediatr. 1992;29:1203-82; Reproduced with permission.

adolescents with chronic undernutrition and energy deficiency is associated with functional gonadotropin deficiency, possibly from an apparently dormant hypothalamic gonadotropin-releasing hormone pulse generator.

Leptin is a hormone produced from fat cells and reflects energy stores. It is a critical hormone that provides signals to the hypothalamus about the nutritional state, and in turn regulates appetite and body weight. It also has other influences on the hypothalamus that affects a number of pituitary hormones, notably GH, gonadotropins and adrenocorticotrophic hormone (ACTH). In undernourished children, circulating leptin levels are low and correlate with low insulin, high GH but low IGF-1 concentrations, low gonadotropins and high cortisol levels. This endocrine milieu facilitates the adaptation from carbohydrate to fat-based metabolism by augmenting fatty acid mobilization, proteolysis and gluconeogenesis. These adaptive endocrine effects from chronic undernutrition are partly reversed by nutritional recovery but sustained weight gain is required for linear growth to improve.

### Chronic Systemic Disease

Growth impairment is a well-recognized feature of any unremitting or relapsing chronic systemic condition (**Fig. 1**). Delayed puberty due to functional gonadotropin deficiency in such conditions can further exaggerate the impairment in height in adolescents. Short stature can be the presenting feature in conditions such

as celiac disease, chronic inflammatory bowel disease, chronic infections like HIV and renal tubular acidosis. The severity and duration of growth impairment will depend on the nature, course, complications, management and response to treatment of the underlying disease. Catch-up in growth and attainment of normal height can be expected for conditions that can be successfully managed (e.g., gluten free diet in celiac disease). However, growth outcome remains guarded for other conditions that are refractory, associated with major complications, not easily treatable (e.g., chronic renal failure), not responsive to treatment or where treatment itself has adverse effects on growth (e.g., corticosteroids). The pathophysiology of growth impairment in chronic systemic disease is multifactorial. Chronic undernutrition, inflammation and prolonged corticosteroid treatment disrupt the functional integrity of the GH-IGF-1 axis and give rise to a state of relative GH resistance.

Proinflammatory cytokines are implicated in playing an important role in increased energy expenditure, fat mobilization, proteolysis, negative nitrogen balance, gluconeogenesis, anorexia and weight loss seen in chronic inflammation. However, reduced growth in chronic inflammation occurs even when nutrition is adequately supplemented and highlights a modulatory effect of the cytokines on the integrity of the GH-IGF-1 axis and direct local effect on the epiphyseal growth plate. Levels of proinflammatory cytokines, interleukin-6 (IL-6), tumor necrosis factor  $\alpha$  (TNF $\alpha$ ) and IL-1 $\beta$ , are high in a number of chronic inflammatory conditions (juvenile chronic arthritis, inflammatory bowel disease, cystic fibrosis), correlate with the severity of the underlying condition and are associated with GH resistance (normal or high GH but low levels of IGF-1 and IGFBP-3).

The immunosuppressive and anti-inflammatory properties of corticosteroids are of benefit in the treatment of specific chronic diseases. However, long-term treatment carries the risk of growth impairment. The adverse effects of corticosteroids on linear growth are mediated through complex processes and include disruption of the GH-IGF axis, direct effects on the epiphyseal growth plate,

inhibitory effects on gonadotropin secretion and suppression of endogenous adrenal corticosteroid production.

### *Intrauterine and Early Postnatal Growth Retardation*

Intrauterine growth retardation (IUGR), being born small for gestational age (SGA) as well as wasting and stunting in early childhood are common problems in India. Among the numerous contributing factors, maternal ill health (especially from communicable diseases), poor nutrition and adverse lifestyles (such as smoking) during pregnancy and lactation remain most significant. While most infants with a history of IUGR show catch-up growth in first 2–4 years, approximately 10% infants do not catch-up and thus remain short.

IUGR with poor postnatal growth and short stature is also a feature of specific syndromes such as Russell-Silver and 3-M, both clinically and genetically heterogeneous (**Table 2**).

### *Endocrine Disorders*

**Hypothyroidism** Short stature due to growth failure is among the characteristic features of hypothyroidism in children, irrespective of the underlying cause. Although hypothyroidism is most commonly primary due to pathology in the thyroid gland, it can also be secondary due to pituitary thyroid-stimulating hormone (TSH) deficiency or tertiary due to a hypothalamic defect in thyrotropin-releasing hormone (TRH) secretion.

Primary hypothyroidism can be congenital or acquired. The causes of primary acquired hypothyroidism include autoimmune thyroiditis (Hashimoto) and iodine deficiency. Children with these conditions may have goiter.

In countries where neonatal screening has been implemented, primary congenital hypothyroidism is diagnosed in the first few weeks of life from raised blood TSH levels. This means that thyroxine (T4) replacement can be started in the neonatal period. Provided these children are appropriately managed and compliance with thyroxine replacement is good, they are unlikely to develop short stature. In countries such as India where there are no national

**Table 2** Characteristic features of genetic short-stature syndromes associated with a child being born small for gestational age

Characteristics	Russell-Silver syndrome	3-M syndrome
Estimated incidence	1 in 3,000–100,000 and male predominance	Rare autosomal recessive primordial growth disorder
Growth characteristics	IUGR, SGA and poor postnatal growth; short and lean with poor weight gain; relative macrocephaly; limb length asymmetry; hemihypertrophy	IUGR, SGA and poor postnatal growth; short and lean; relative macrocephaly
Pubertal development and adult height	Onset of puberty normal or early short adult height (average F: 140 cm; M: 150 cm)	Normal age of onset of puberty; short adult height
Facial features	Prominent forehead, small triangular face, bluish sclera, downturned corners of the mouth, small jaw and narrow chin	Frontal bossing, small triangular face with midfacial hypoplasia, full eyebrows, fleshy nose tip, anteverted nares, long philtrum, full fleshy lips, pointed chin, short broad neck
Other features	Feeding difficulties from birth, clinodactyly, café-au-lait patches	Short chest with sternal deformity, fleshy prominent heels, slender bones, relatively tall vertebral bodies, dysplastic hips, joint hypermobility
Genetics	Defects on chromosomes 7 and 11 in 50% cases; hypomethylation of <i>H19</i> differentially methylated region at the 11p15 locus in 40–50% cases; 10% have maternal uniparental disomy of chromosome 7	Defects in three separate genes have been identified in cases with 3-M syndrome: <i>CUL7</i> mutations in about 70%; <i>OBSL1</i> mutations in 25%; <i>CCDC8</i> mutations 5%
GH-IGF status	Normal GH levels to stimulation tests but abnormalities in 24-hour spontaneous GH secretion; low IGF-1 and IGFBP-3 levels indicate abnormal GH secretion and relative GH insensitivity	Normal GH levels to stimulation tests; relatively low IGF-I levels indicate relative GH insensitivity
Management	Potential for attaining normal adult height with GH treatment in some patients	No significant improvement in height with growth hormone treatment

Abbreviations: IUGR, Intrauterine growth retardation; SGA, small for gestational age.

screening programs, children with congenital hypothyroidism may present with short stature after the first few years of life.

In addition to short stature, children with hypothyroidism may appear relatively overweight. Clues to the diagnosis include delay in achieving developmental milestones, drowsiness, lethargy, apathy, poor concentration and slow academic progress. Although constipation is a feature of hypothyroidism, it is also a common problem in otherwise healthy children. Other important history and examination findings are coarse facial features, hoarse voice, rough dry skin, cold intolerance, mottled skin, bradycardia, slow relaxation of deep tendon reflexes and delayed bone age.

Thyroid function with both TSH and free T<sub>4</sub> (or total thyroxine) level is the most important investigation and will help confirm the clinical suspicion of hypothyroidism and whether it is primary or secondary. Although establishing the underlying cause of hypothyroidism requires additional investigations, these are not critical if resources are limited and should not detract from starting T<sub>4</sub> replacement.

**Growth hormone deficiency (GHD)** It can be isolated or associated with other pituitary hormone deficiencies. Growth failure leading to a decline in a child's height centile and consequently short stature is the most salient feature in children with GHD (**Fig. 1**). This is especially important to recognize because it may be the only overt finding that helps distinguish isolated idiopathic GHD from FSS or CDGP.

In preschool age children, the most common cause of GHD is a congenital or genetic defect in hypothalamic pituitary development or function, such as septo-optic dysplasia. Acquired causes need to be considered in older children and adolescents. However, no definite cause is identified in many cases.

In addition to the distinct growth pattern, history and examination can provide clues suggestive of GHD and the underlying etiology (**Table 3**).

**Growth hormone insensitivity** GH insensitivity is defined as high GH levels to stimulation tests and low IGF-1 levels. Acquired GH insensitivity occurs in chronic undernutrition, systemic disease and inflammation, as described earlier. Congenital GH insensitivity can be due to defects in the GH receptor, GH signaling, IGF-1 gene or its receptor. Children with these defects are exceptionally short and have clinical features similar to GHD. Head size is normal in GH receptor and signaling defects but small in children with defects in the IGF-1 gene or its receptor.

**Cushing syndrome** Corticosteroids are used long-term to manage a wide range of conditions such as intractable asthma, nephrotic syndrome, juvenile chronic arthritis and inflammatory bowel disease. Growth impairment and short stature are well recognized side effects of prolonged treatment with systemic corticosteroids

and also reported with potent inhaled corticosteroids. Excess endogenous corticosteroid secretion from primary adrenal pathology or secondary to increased pituitary ACTH secretion (Cushing disease) is rare in children.

### Genetic Syndromes

The major genetic syndromes characterized by short stature are Down syndrome, Turner syndrome, Noonan syndrome, Aarskog syndrome and Prader-Willi syndrome. The salient distinguishing features are presented in **Table 4**.

**Down syndrome** In addition to the chromosomal defect, the factors contributing to short stature are hypothalamic dysregulation of growth hormone secretion, coexisting systemic problems, especially symptomatic heart disease, autoimmune problems such as hypothyroidism and celiac disease, and an attenuated pubertal growth spurt.

**Turner syndrome** Two copies of the *SHOX* gene are required for normal growth in height and the chromosomal defect with a single copy of the *SHOX* gene explains the short stature in this syndrome. Defects in both copies of the *SHOX* gene are associated with severe short stature and found in Léri-Weill dyschondrosteosis.

Presentation of Turner syndrome can be antenatal (nuchal fold on ultrasound examination), at birth (lymphedema, coarctation of the aorta), school age (short stature which becomes more obvious after age 3–4 years) or adolescence (delayed or arrested puberty, primary hypothyroidism). Clinical features in girls with Turner syndrome vary considerably but the single consistent feature in all is short stature and reduced adult height (136–147 cm). The syndrome should therefore be considered in any girl presenting with short stature. Treatment with growth hormone can improve final height. However, in resource limited settings the priority is to identify and manage life limiting abnormalities such as coarctation of the aorta. In addition, primary ovarian failure necessitates estrogen replacement to enable pubertal maturation and optimize bone health.

### Skeletal Dysplasia (Osteochondrodysplasias)

Skeletal dysplasias are a heterogeneous group of disorders that affect cartilage and bone, and can present with disproportionate short stature. The most widely recognized among these are the two autosomal dominant conditions achondroplasia and hypochondroplasia due to mutations in *FGFR3*. Hypochondroplasia is less striking than achondroplasia, and the disproportion may only be evident when sitting height and subischial leg length are plotted on charts. Other features notable in achondroplasia such as large head and lumbar lordosis may also be subtle. A skeletal survey helps in establishing the diagnosis.

**Table 3** Clues from the history and examination that suggest growth hormone deficiency (GHD) and the underlying etiology

Characteristics	Features suggestive of GHD	Clues to underlying etiology
Symptoms	Declining height centile, short stature, tiredness	Morning headache, persistent vomiting, visual impairment, squint, nystagmus
Birth and neonatal history	Hypoglycemia, prolonged jaundice	Breech or traumatic delivery
Childhood events		Head injury, intracranial infection, cranial irradiation
Family history		Consanguinity, exceptional short stature
Examination	High pitched voice, cherubic face with crowding of mid facial structures, normal head circumference and frontal bossing, chubbiness with more subcutaneous fat compared to muscle bulk, anterior abdominal adiposity with dimpling of fat, small phallus and nonpalpable testes (where gonadotropin deficiency is coexistent), delayed bone age, delayed dentition, delayed puberty	Visual field defect, features to suggest other pituitary hormone deficiencies such as midline abnormalities: cleft lip/palate, single central incisor, optic nerve hypoplasia

**Table 4** Salient distinguishing features of syndromic causes of short stature

	<i>Down syndrome</i>	<i>Turner syndrome</i>	<i>Noonan syndrome</i>	<i>Aarskog syndrome</i>	<i>Prader–Willi syndrome</i>
Growth characteristics	Normal birth size, decline in height centiles evident from age 6 months–3 years, tendency to obesity, relatively short limbs, mean adult height 168 cm in males and 142 cm in females	Birth size normal, decline in height centiles evident by age 3–5 years, relatively short limbs, mean adult height 140 cm	Birth size normal, short stature evident in childhood, adult height can vary from normal to short stature	Birth size normal, short stature evident by age 1–3 years, adult height normal	Birth size normal, feeding difficulties and poor weight gain in infancy, obsessive food seeking behavior, insatiable appetite and excessive weight gain evident from age 2–3 years, adult height can vary from normal to short stature (mean 162 cm in males, 150 cm in females)
Pubertal development	Relatively early, attenuated pubertal growth spurt	Majority will not start puberty spontaneously, no pubertal growth spurt	Delayed in males, attenuated pubertal growth spurt	Delayed, good catch-up in height during puberty	Delayed
Facial features	Flat face, eyes slant upwards and outwards, epicanthic folds, depressed nasal bridge, small nose, small mouth and large tongue	Down-slanting eyes, low set ears, high arch palate, neck webbing, low posterior hairline	Eyes wide spaced, ptosis, low set ears, broad nasal tip, grooved philtrum, high arch palate, small jaw, short webbed neck, low posterior hairline	Round flat face, broad forehead with widow's peak, eyes wide spaced, short broad upturned nose, anteverted nostrils, long philtrum, thin short upper lip, large broad upper incisors in permanent dentition, maxillary hypoplasia	Almond shaped eyes, fair hair
Other features	Hypotonia, broad hands and short fingers, single transverse palmar crease, sandal gap between 1st and 2nd toes	Cubitus valgus, hyperconvex hypoplastic nails, multiple naevi, broad chest and wide spaced nipples	Undescended testes, sternum deformities, café-au-lait spots	Short broad hands and feet, broad thumbs and big toes, hyperextension at proximal and flexion at distal interphalangeal joints (swan neck appearance), interdigital webbing, ventral scrotal folds encircling penis (shawl scrotum), undescended testes	Learning difficulties, floppiness from birth, increased fat mass compared to lean mass, small hands and feet, undescended testes and underdeveloped genitalia, scoliosis
Associated problems	Mild to moderate learning difficulties, congenital heart defects, gastrointestinal defects, thyroid dysfunction, myopia, hearing impairment	Specific learning difficulty, primary ovarian failure, left sided heart defects, renal abnormalities, ear infections and hearing impairment, autoimmune hypothyroidism	Mild learning difficulties, right sided heart defects (pulmonary stenosis), hypertrophic cardiomyopathy, bleeding tendency	Mild to moderate learning difficulties, hyperactivity and attention deficit	Mild to moderate learning difficulties, high pain threshold and self-mutilating behavior, type 2 diabetes

### Approach to Diagnosis

When assessing a child with short stature or concerns about growth, serial measurements of the child's height/length, weight and head circumference as well as measured (preferably) or reported heights of natural parents should be obtained and plotted on population specific growth charts (**Figs 1 and 2**). This helps to differentiate true short stature and growth failure from perceived short stature. Such a record is also vital for monitoring health status, disease activity, adverse clinical events and response to treatment.

The age of the child when concerns about growth in height were first aroused and pubertal status during the adolescent years gives some clues to the etiology (**Table 5**). A family history along with heights of parents and other family members helps differentiate whether the problem is familial. Consanguinity raises the possibility of an inherited condition.

The most prominent presenting complaint or clinical feature provides a helpful clinical classification of short stature (**Table 6**). This also aids in gathering hypotheses generated information from a focused history and examination. In addition to potential causes, the impact of short stature on the individual's physical and psychological wellbeing, their concerns and expectations, should

be elicited. These will need to be taken into consideration when deciding on further management.

Maternal nutrition, health (e.g., rubella, malaria), lifestyle (e.g., alcohol, smoking) and treatment can affect fetal growth and birth size. These should be explored in children with a history of poor growth in utero and those born small for gestational age. Salient features to elicit in the postnatal history include prolonged jaundice (congenital hypothyroidism, congenital hypopituitarism), neonatal hypoglycemia (congenital hypopituitarism), floppiness and feeding difficulties (Prader–Willi syndrome), puffy hands and feet (Turner syndrome).

A detailed medical history should provide clues for chronic energy deficiency (inadequate dietary intake or malabsorption) and chronic systemic illness, recurrent infections (malaria, respiratory tract infections, urinary tract infections and gastroenteritis). Short stature can be due to the medical problem as well as adverse effects of treatments, such as prolonged systemic corticosteroids and frequent blood transfusions (for chronic hemolytic anemia).

Concerns about neurodevelopment in global or specific aspects of hearing and language, vision (e.g., septo-optic dysplasia), motor, cognitive (e.g., Prader–Willi syndrome) and

social development raise the possibility of syndromes. In addition to specific findings of the most likely diagnoses suspected from the elicited history, general examination should include:

- Nutritional status and muscle bulk
- Skin for nevi (Turner syndrome) and café-au-lait spots (Fanconi anemia, Russell-Silver syndrome, Noonan syndrome), pigmented macules (neurofibromatosis type 1).

**Table 5** Clues to causes of short stature according to the age of onset

Age when short stature first noted	Causes of short stature
Birth to 2 years	<ul style="list-style-type: none"> <li>• Familial short stature</li> <li>• Chronic undernutrition owing to lack of food (poverty), inadequate dietary intake (e.g., feeding difficulties), malabsorption (e.g., chronic diarrhea, giardiasis, celiac disease), unmet high metabolic requirements (e.g., chronic lung disease)</li> <li>• Rickets</li> <li>• Skeletal dysplasia</li> </ul>
2–5 years	<ul style="list-style-type: none"> <li>• Untreated congenital hypothyroidism</li> <li>• Growth hormone deficiency, e.g., isolated, congenital hypopituitarism</li> <li>• Turner syndrome</li> <li>• Chronic renal failure and other chronic systemic diseases</li> </ul>
5–9 years	<ul style="list-style-type: none"> <li>• Constitutional delay in growth</li> <li>• Chronic systemic conditions, e.g., poorly controlled asthma, acquired heart disease (e.g., complication of rheumatic fever)</li> </ul>
9 years and older	<ul style="list-style-type: none"> <li>• Familial short stature</li> <li>• Constitutional delay</li> <li>• Chronic systemic conditions</li> <li>• Acquired primary hypothyroidism</li> <li>• Acquired growth hormone deficiency, e.g., tumor, trauma, surgery, radiotherapy</li> </ul>

- Head size (relatively large in Russell-Silver syndrome)
- Face and neck (characteristic features in Turner syndrome, Noonan syndrome, fetal alcohol syndrome)
- Hands and limbs (radial abnormalities in Fanconi anemia, dinner fork deformity of forearm in Léri-Weill dyschondrosteosis)
- Body symmetry and proportions (short limbs and arms shorter than forearms in achondroplasia and hypochondroplasia, leg length discrepancy in Russell-Silver syndrome)
- Signs of chronic systemic illness.

## Investigations

Specific investigations should be considered when clues point to pathological causes. In the absence of such clues along with normal weight gain a pathological cause is unlikely and investigations are not required. This is further supported by normal height velocity (evaluated from reassessment at 3–6 monthly intervals) during follow-up and a normal bone age. In all cases with low growth velocity and/or delayed bone age, screening investigations should be done since some disorders may present with growth failure as their only manifestation (**Fig. 1**). These include a hemogram, erythrocyte sedimentation rate (ESR), liver and kidney function tests, venous blood gas analysis, thyroid function tests and serology for celiac disease. A karyotype should be done in all girls with unexplained short stature to check for Turner syndrome should be done. A delayed bone age heralds good potential for future growth and can be reassuring for subjects with CDGP (**Fig. 2**).

## Management

In addition to the specific management of the underlying pathology, management of a child with short stature entails addressing physical and psychological concerns (**Fig. 3**). The two growth promoting treatments that are available, namely recombinant human growth hormone and recombinant IGF-1, have specific indications (**Table 7**). However, these treatments are

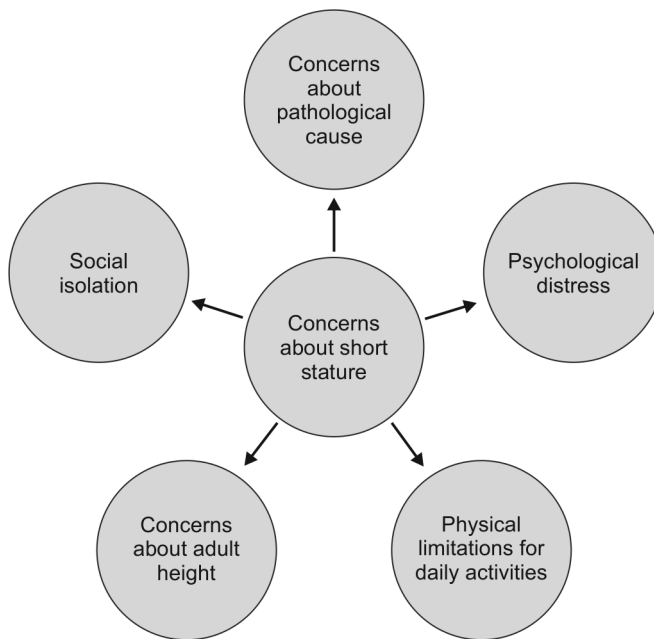

**Table 6** Classification for causes of short stature categorized by the most prominent presenting complaint or clinical feature

Most prominent clinical feature	Other distinguishing features	Causes of short stature
Otherwise healthy child, height velocity normal for stage of puberty and no growth failure	Family history of short stature, no bone age delay	Familial short stature
	Family history of delayed puberty, bone age delayed	Constitutional delay in growth and puberty
Born small for gestational age	Head size normal or relatively large	Russell-Silver syndrome, 3-M syndrome
	Small head	Congenital infections such as rubella; fetal alcohol spectrum disorder; Fanconi anemia
Chronic systemic disease	Overt features of underlying problem	Undernutrition, chronic infection; chronic gastrointestinal disease; symptomatic congenital or acquired heart disease; chronic renal failure
	Occult or asymptomatic problem	Celiac disease; renal tubular defects
Endocrine disorder	Features of underlying problem	Hypothyroidism; growth hormone deficiency; primary IGF-1 deficiency
	Adverse effect of treatment	Excess corticosteroids
Dysmorphic features	Girls	Turner syndrome; SHOX deficiency (Léri-Weill dyschondrosteosis or Langer mesomelia)
	Girls or boys	Down syndrome; Noonan syndrome; Prader-Willi syndrome
	Boys	Aarskog syndrome
Disproportion between trunk (sitting height) and limbs (subischial leg length)	Short limbs	<i>Skeletal dysplasias</i> : Hypochondroplasia, achondroplasia
	Short trunk	Mucopolysaccharidosis type 4 (Morquio syndrome), type 2 (Hunter syndrome); osteogenesis imperfecta
Long-term medication	Features of the condition being treated	Corticosteroids; stimulants such as methylphenidate

**Table 7** Evidence-based indications for recombinant human growth hormone and recombinant insulin-like growth factor 1 (IGF-1)

Indications for recombinant human growth hormone treatment	Indications for recombinant IGF-1 treatment
Growth hormone deficiency Turner syndrome SHOX haploinsufficiency Exceptional short stature in a child born small for gestational age Chronic renal failure Prader-Willi syndrome	Primary IGF-1 deficiency

**Figure 3** The different facets of concerns about short stature

costly and ethical considerations alongside potential benefits and risks must be discussed with families.

## TALL STATURE

Tall stature is considered when height is greater than 2 SD above the population mean for age and sex (using growth charts based on local reference standards) or where there is a significant discrepancy between the mid-parental centile and child's height. A detailed assessment of tall stature by the endocrinologist is essential to predict final adult height, exclude any underlying disorder and provide treatment if needed.

### Etiology and Epidemiology

The causes of tall stature are listed in **Table 8**. Familial tall stature (or constitutional tall stature) is the most common cause of tall stature in children and adolescents.

### Clinical Approach

#### History

A detailed history of the child's growth including birthweight and length and the pattern of early growth should be obtained. Birthweight and length are usually above 2 SD in children with primary growth disorders, such as Sotos, Beckwith-Wiedemann and Marfan syndromes. They continue to show accelerated growth velocity in infancy and early childhood. Conversely,

**Table 8** Causes of tall stature

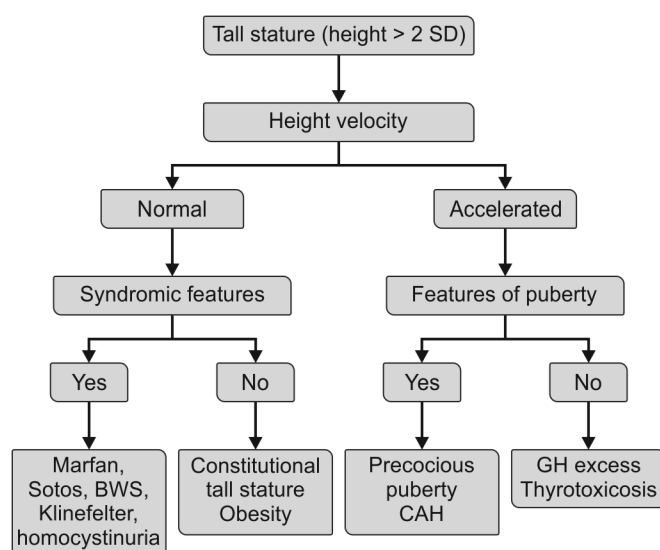

Primary	Sex chromosome abnormalities	Klinefelter syndrome (47,XXY) and variants
	Overgrowth syndromes	Sotos syndrome; Weaver syndrome; Beckwith-Wiedemann syndrome
	Genetic syndromes with tall stature	Marfan syndrome; Multiple endocrine neoplasia 2B (MEN 2B)
Secondary	Endocrine causes	Growth hormone (GH) excess; thyrotoxicosis; precocious puberty Adrenal tumor; hypogonadism; androgen insensitivity; defects of estrogen production; isolated ACTH insensitivity; congenital adrenal hyperplasia
	Metabolic causes	Homocystinuria
Constitutional	Familial tall stature	
Others	Exogenous ('Simple') obesity	

children with constitutional tall stature are within the normal range for birthweight and length and demonstrate accelerated growth velocity in early childhood. Neonatal hypoglycemia can be a feature of Beckwith-Wiedemann syndrome. An underlying endocrine disorder is suspected when the growth initially follows a lower centile and then crosses up the growth chart centiles. A history of excessive weight gain, eating habits and pubertal history should be taken in all cases. Simple obesity can lead to tall stature and advanced bone age. Children with hyperthyroidism may be noted to cross down weight centiles. Symptoms of hyperthyroidism include palpitations, muscle weakness, diarrhea, weight loss, heat intolerance. A history of ophthalmic problems, including lens subluxation, retinal detachment and glaucoma can suggest Marfan syndrome or homocystinuria. Visual impairment may be noted in a growth hormone secreting tumor. Developmental delay and learning difficulties can be features of children with homocystinuria, Sotos and Klinefelter syndromes.

#### Physical Examination

Physical examination must include auxology, examination for features of syndromic and systemic causes and pubertal staging. Obtaining the height of each biological parent, sibling and other family members is necessary. It is essential to calculate mid-parental height and target centile range for final adult height. A significant discrepancy between the child's height and mid-parental centile points towards a growth disorder than constitutional tall stature. Sitting height and arm span should be measured. Marfan and Klinefelter syndromes are associated with disproportionate tall stature. Arm span is greater than height in Marfan and Sotos syndromes. Head circumference is greater than 2 SD in most patients with Sotos syndrome. Precocious puberty is associated with an early pubertal growth spurt, but results in a shorter than expected final height due to the premature closure of the epiphyses. Tremor, tachycardia, diarrhea, hair loss, exophthalmos and goiter are signs of thyrotoxicosis. GH-secreting pituitary adenoma can present with bitemporal hemianopia. Sotos syndrome is characterized by dysmorphic features like prominent forehead, hypertelorism, large ears and high arched palate. Macroglossia and earlobe creases are features of Beckwith-Wiedemann syndrome.

A diagnostic approach to the assessment of tall stature is shown in **Figure 4**.

**Figure 4** Diagnostic approach to the evaluation of tall stature

Abbreviations: SD, standard deviation; GH, growth hormone; CAH, congenital adrenal hyperplasia; BWS, Beckwith–Wiedemann syndrome.

## Differential Diagnosis

### Constitutional (Familial) Tall Stature

The features of constitutional tall stature include tall stature in one or both parents, predicted adult height within mid-parental target range and normal height velocity. The birth length is usually normal and the tall stature usually becomes apparent from 3 years to 4 years of age. It results in increased final height within the range defined by parental size. Tall stature may not arouse undue concern in a family with tall individuals. It is also perceived as socially advantageous and more acceptable than short stature especially in males. Thus females with tall stature are more likely to seek medical help than males. Physical examination is normal and there is a normal age of onset of puberty. The legs are often relatively long in comparison to sitting height. Assessment of bone age (which is likely to be advanced) and calculation of final height prediction may be helpful. The management will predominantly involve reassurance.

### Obesity

Exogenous (*simple*) obesity is a becoming a global epidemic. It can be associated with tall stature and advanced bone age, although the final height does not appear to be increased. Excess calorie intake is available for growth and may produce relatively tall stature (at upper end of predicted target range). Striae and a high cheek color may mimic mild Cushing syndrome. However, unlike Cushing and other endocrine causes of obesity, where affected children are characteristically short, exogenous obesity is associated with tall stature and with elevated levels of serum insulin concentrations. Insulin acting at the IGF-1 receptor in the skin produces acanthosis nigricans. Treatment is aimed at weight reduction (with calorie restriction and increased physical activity).

### Klinefelter Syndrome

It is caused by an extra sex chromosome (47,XXY) due to nondisjunction during meiosis. The incidence is around 1 in 1,500 males. The clinical features include tall stature, eunuchoid body proportions (increased arm span to height ratio), hypogonadism with small testes (secondary to tubular hyalinization), pubertal failure or arrest, gynecomastia, behavioral problems and learning

**Table 9** Clinical features of Marfan syndrome

System	Clinical features
Skeletal	Long arms (arm span > 5 cm than the height), long legs compared to the back (reduced US/LS ratio), arachnodactyly, joint laxity (wrist and thumb sign) Scoliosis and chest deformities (pectus excavatum or carinatum), high arched palate and flat feet
Eyes	Myopia, upward dislocation or poor fixation of the lens, flat cornea and hypoplastic iris
Cardiovascular	Mitral and aortic valve incompetence, peripheral pulmonary stenosis Aortic root dilatation and dissection
Chest	Spontaneous pneumothorax
Skin	Hernia, striae

Abbreviations: US, upper segment; LS, lower segment.

difficulties. The legs are relatively long compared to the back, especially with late diagnosis or after failure of puberty.

The other sex chromosomal variants associated with tall stature include 47,XYY, 47,XXX, 48,XXXY, 48,XXYY and 49,XXXXY.

### Marfan Syndrome

Marfan syndrome is an autosomal dominant condition of the connective tissue caused by mutations in the fibrillin gene FBN1 located on chromosome 15q21. The incidence is 1 in 5,000–10,000. It is characterized by disproportionate tall stature and the clinical features involve a number of systems as detailed in **Table 9**. The features can vary from mild to severe and the cardiac defects are the most serious complications of Marfan syndrome.

### Homocystinuria

Homocystinuria is an autosomal recessive disorder of the metabolism of the amino acid methionine which results in an abnormal accumulation of homocysteine and its metabolites in the blood and urine. It is associated with disproportionate tall stature but usually presents with marked learning difficulties, ectopia lentis (downward dislocation of the lens) and severe myopia with later thromboembolic and cardiovascular complications.

### Sotos Syndrome (Cerebral Gigantism)

Sotos syndrome is an autosomal dominant condition caused by mutations in the *NSD1* gene. It is characterized by excessive prenatal and postnatal growth, increased birthweight, tall forehead, large head circumference, a high arched palate, down slanting palpebral fissures, flushed cheeks, large chin, large hands and feet, scoliosis and developmental delay of variable severity. Individuals are tall during childhood but attain normal adult height owing to an advanced bone age.

### Beckwith–Wiedemann Syndrome

Beckwith–Wiedemann syndrome is an autosomal dominant condition caused by dysregulated expression of imprinted genes in the region 11p15.5. The pancreas is hyperplastic and can lead to neonatal hypoglycemia secondary to hyperinsulinism. It is an overgrowth disorder characterized by macrosomia, macroglossia, hemihypertrophy, transverse ear crease, organomegaly and omphalocele. It can be associated with tumors like Wilms tumor, hepatoblastoma and germ cell tumors.

### Growth Hormone Excess

Excessive GH production prior to fusion of the epiphyses leads to pituitary gigantism which is exceptionally rare. It can be due

to a GH-producing adenoma in the pituitary or GHRH excess from hypothalamic tumors. Pituitary hyperplasia with excess GH secretion may be seen as part of McCune-Albright syndrome and Carney complex (a rare disorder characterized by myxomas, lentigenes, endocrine and nonendocrine tumors). Although the most common pituitary tumors in multiple endocrine neoplasia (MEN) type 1 are prolactinomas, GH secreting adenomas may also occur. Familial acromegaly and familial isolated pituitary adenomas are rare conditions of GH excess due to dominantly inherited mutations in aryl hydrocarbon interacting protein. A proportionate, worsening tall stature with a rapid height velocity is a feature of all these conditions. GH excess causes prominent soft tissues, prognathism, frontal bossing, large hands and feet and signs and symptoms resulting from optic chiasm compression caused by the pituitary tumor. In the absence of treatment, adult heights up to 247 cm in the female and 274 cm in the male may be found. Concentrations of GH and IGF-1 are high and the GH does not suppress in response to a glucose load.

### Other Endocrine Abnormalities

Precocious puberty (both central and peripheral) can be characterized by tall stature, although the final height is compromised if untreated. Thyrotoxicosis can lead to rapid growth and advanced bone age. Aromatase deficiency resulting from mutation of the *CYP19* gene prevents the conversion of testosterone to estrogen in the male and hence there is lack of

epiphyseal fusion. These males continue growing into adulthood and have osteoporosis and delayed bone age.

### Investigations

The history and examination will guide further investigations. Most children may not require extensive investigations apart from regular growth and pubertal monitoring at intervals of 6 months. Constitutional tall stature and primary growth disorders generally demonstrate normal growth velocities, whereas secondary growth disorders will be characterized by accelerated growth velocity. Estimation of bone age will help to estimate skeletal maturation and calculate predicted height. Advanced bone age may be seen in constitutional tall stature, obesity, precocious puberty, thyrotoxicosis and Sotos syndrome. Delayed bone age can be noted in hypogonadism. Further investigations, like measurement of T4 and TSH, IGF-1, GH suppression test, magnetic resonance imaging (MRI) pituitary, 9 am cortisol, prolactin urinary and total plasma homocysteine levels may become necessary based on the initial evaluation. Investigations of precocious puberty and congenital adrenal hyperplasia (CAH) should be guided by the initial assessment. In the presence of behavioral or learning difficulties a karyotype should be performed. If there is a suggestion of MEN2B from the family history or examination (presence of mucosal neuromas in a child with a marfanoid habitus), it is essential to measure calcitonin concentration and to confirm the diagnosis by analysis of the ret-proto-oncogene.

**Figure 5** Adult height of males and females with a range of conditions that significantly affect stature. These are illustrated in comparison to normal stature of western populations and healthy Indians

## Management

The management of constitutional tall stature will include reassurance to address the parental anxieties and providing an estimate of final adult height (**Fig. 5**). Medical intervention is generally not necessary. It can be considered for children in whom the tall stature or predicted adult height is expected to have significant psychosocial consequences. Tall children can feel different from their peers and are likely to be teased about their height. Some experts recommend height reduction with medical treatment that requires use of high doses of exogenous sex steroids. Although treatment is most effective when initiated at both lower chronological and bone age, it is not recommended before the normal age of puberty. In adolescent girls ethinyl estradiol orally combined with cyclic progesterone can reduce final height by around 7 cm. Similar results have been found in boys with high dose intramuscular testosterone. Side effects of estrogen include weight gain, acne headaches, dysmenorrhea, and venous thromboembolic events. Side effects of testosterone include behavior problems, weight gain, gynecomastia and acne. Surgical epiphysiodesis (surgical ablation of growth plate) has occasionally been undertaken in rare cases.

The pitfalls in the management of tall stature include failure to examine the patients carefully for dysmorphic features suggestive of Marfan syndrome. This diagnosis may have serious consequences as these patients need life-long cardiovascular surveillance. Failure to appreciate that tall stature and delayed puberty are an unusual combination can lead to delayed diagnosis of Klinefelter syndrome.

## IN A NUTSHELL

1. Accurate auxology, calculation of height velocity, evaluation with pubertal status, comparison with parents' heights (using local growth reference standards) thorough clinical consultation are essential for the assessment of short and tall stature and other growth disorders.
2. Familial and constitutional short/tall statures are the most common causes of deviations in stature and are characterized by normal height velocity.
3. Follow-up evaluation is crucial in identifying decline or acceleration in height velocity. This along with other clues such as body disproportions, dysmorphic features and systemic problems suggest underlying pathology and warrant further investigations.
4. Expert advice from a pediatric endocrinologist should be sought before embarking on specific growth promoting or suppressing treatments.

## DEVELOPMENT AND DEVELOPMENTAL DELAY

**Section Editors** Anand Pandit, Sudha Chaudhari

### Chapter 20.1

## Introduction to Development, Laws of Development, and Factors Affecting Development

Satnam Kaur

### INTRODUCTION TO DEVELOPMENT

Development, or more precisely *neurodevelopment*, refers to a process of functional maturation and acquisition of new skills related to maturation of neural structures. It refers to the qualitative changes occurring in a progressive, orderly and coherent manner that enable the child to function on a higher level. Progressive denotes that changes are unidirectional (forward). Orderly and coherent signify that attainment of a particular skill builds on achievement of earlier skills and skills are not skipped. It is different from *growth* that connotes quantitative changes of increase in size and structure and refers to measurable quantities such as weight and height.

### Process of Development

Development is a continuous process that starts in utero and continues postnatally and birth is just a transitional event between the two. As early as 8–9 weeks of gestation, isolated muscular contractions in response to local stimulus may be seen. By 13–14 weeks, graceful flowing movements may be produced by stimulation of all areas except back and vertex and mother may feel fetal movements. Breathing and swallowing movements appear at about the same time. Grasp reflex appears at about 17 weeks and is well developed by 27 weeks. Response to sound and eye-opening appear at about 26 weeks. During the third trimester, the fetus responds to external stimuli by elevation of heart rate, and movements and reactivity varies depending on behavior state as is seen in a neonate. Habituation (repeated stimulation causing progressively decreased responsiveness) can be demonstrated in late pregnancy. This orderly development continues into infancy and childhood with mastery over increasingly complex tasks and transforms a totally dependent baby into a fully independent person. However, it is continuously influenced by intrinsic and extrinsic factors as discussed subsequently. Thus, development occurring in infancy and childhood is truly remarkable. During this period, the child learns to move about and explore the environment (motor development), builds up knowledge (cognition), learns to communicate (language) and develops a sense of self, learns to control his emotions and to adapt to his social environment (personal-social).

Development is a qualitative process and is not something that can be measured using a weighing scale or ruler. Nonetheless, it can be observed, assessed and followed over time. Developmental

milestones provide a systematic approach to study the neuro-developmental sequences and to observe the progress of a child over time. Milestones have been organized into four domains—motor (gross motor and fine motor), cognitive/adaptive, language, and personal-social—for the ease of assessment. However, they are all interrelated and delay in one domain may impair development in another domain. For example, a neuromuscular disorder will not only affect motor development but also affect cognitive development by interfering with ability to explore the environment.

### Theories of Development

Several theories about child development have been proposed and have influenced our understanding of child development. Each theory provides some insights into how children grow and develop. Some of the key theories that have helped shape our understanding of development are described here.

#### *Maturational Theory by Arnold Gesell*

As per this theory, development occurs in an orderly and predictable sequence that is genetically determined and related to neurological maturation. Gesell provided a time-table of milestones and usual age range for acquiring them. He did not give much importance to environmental influences on development. The real usefulness of this theory is the importance given to neuromaturation and predictable sequence of child development.

#### *Psychoanalytic Theories by Freud and Erikson*

These theories emphasized the importance of early childhood experiences in modeling personality and social development.

As per Sigmund Freud, behavior is controlled by unconscious urges and the three parts of personality are id, ego and superego. Id reflects basic instincts and is the dominant force during infancy. Ego develops during late infancy and toddler years and is the aware self. Superego or the conscious appears over preschool years. He hypothesized that successful development and integration of these components during early childhood determines adult personality. He stated that each stage has sexual meaning focused on a particular body part. The focus shifts from oral stage (sucking, feeding and biting in infancy) to anal stage (mastery of bowel function in toddler years) to oedipal/phallic stage (interest in genitals and possessiveness toward opposite gender parent). He asserted that successful resolution of sexual conflict of each stage leads to a new level of social and emotional development.

Erik Erikson further built upon Freud's work. He identified eight separate stages of development across lifespan and hypothesized that in each stage the child faces a crisis that must be resolved before moving onto the next stage. The outcome of each stage is determined by the social and cultural environment and caregiving strategies. The stages he described for children include trust versus mistrust (0–18 months), autonomy versus shame and doubt (18 months to 3 years), initiative versus guilt (3–6 years), industry versus inferiority (6–11 years), and identity versus role confusion (adolescent).

### Behavioral and Social Learning Theories (By Ivan Pavlov, JB Watson, BF Skinner, Albert Bandura)

The main premise of these theories is that if behaviors are rewarded, they will repeat. But if behaviors are ignored/punished, they will decrease. These theories give little importance to the child's own emotions/motivations. However, these theories provide an important foundation for some of the interventions used for problematic behaviors like temper tantrums and applied behavior analysis technique used for teaching complex behaviors in children with autism spectrum disorders.

### Cognitive Theories

Jean Piaget postulated that children's thinking passed through four *stages of development* and changed qualitatively in each of these stages. He believed that children were active learners and emphasized the importance of maturation and provision of a stimulating environment for children to explore. Piaget's different stages are as follows:

1. *Sensory-motor stage (0–2 years)* In this stage, children use their motor skills and senses to explore and develop their cognitive abilities. They need to master the concept of object permanence (objects continue to exist even when not in sight), causality, spatial relationships and use of instruments (e.g., using rake to reach for object) before moving onto next stage.
2. *Preoperational stage (2–6 years)* In this stage, children's thinking is egocentric (belief that world revolves around them). They need to understand the sense of animism (objects do not actually have life), egocentrism (he is not the center of the world), idiosyncratic associations and transductive reasoning (things are not necessarily related if they are occurring at the same time).
3. *Concrete operational thinking (6–12 years)* During this stage, children start thinking logically. However, they need concrete materials to help them reach correct conclusions and have trouble imagining hypothetical situations. They need to master the concept of numbers, mass, volume and objective causality.
4. *Formal operational thinking (12 years onward)* In this stage children develop abstract thinking, ability to solve problems in the head and to deal with complex issues.

Lev Vygotsky also proposed that the thinking of children develops in stages, but he emphasized the importance of social and cultural influences on learning. He did not see children as solitary discoverers of knowledge, but believed that the child's cognitive ability was enriched and deepened when they were *scaffolded* by adults. He proposed the term *zone of proximal development* to describe extension of a child's skills with adult help.

Lawrence Kohlberg built on Piagetian framework to describe children's moral problem-solving. He proposed six stages of moral development moving from egocentric behavior in preschool years to conventional morality of adults.

### Importance of Developmental Assessment

Developmental assessment is an integral component of comprehensive child evaluation. A thorough understanding of normal and typical sequence of development allows the clinician to ascertain the child's true developmental status.

- Knowledge of normal development and acceptable variations along with accurate interpretation of clinical examination findings is essential to recognize early patterns that are pathological and may indicate developmental disability. This is especially important for follow-up of *high-risk* babies and children with conditions that may cause brain damage, e.g., babies with perinatal asphyxia, meningitis and metabolic disorders.

- Early recognition of developmental disabilities allows early referral for *early intervention* services and enables the child to attain maximal developmental potential as brain plasticity permits reorganization of neural networks and there are critical *windows of opportunity* for learning different types of skills.
- Normal findings on developmental assessment can be reassuring to parents especially if there is a previous child with developmental disability in the family or before adoption.
- Assessment of behavioral problems also needs knowledge of normal development as behavior can be interpreted in context of a child's level of developmental functioning. For example, temper tantrums normally appear toward end of first year and peak between 2 years and 4 years of age and do not signify behavioral problem.
- Early identification of giftedness can be made on developmental assessment. Gifted children have significantly advanced skills in one domain or other and require optimum environment and educational placement for attaining their full potential.

Thus, developmental pediatrics is concerned not only with children with developmental disabilities but contributes to care of children who are developing normally and those who are at risk for developmental disorders because of medical conditions and adverse environment.

### LAWS OF DEVELOPMENT

Having discussed briefly some general concepts of development and theories of development, we can identify some general principles/laws that govern development.

1. Development is a continuous process from conception to maturity and is related to maturation and myelination of nervous system.
2. Infant development occurs in an orderly and predictable sequence that is intrinsically determined, i.e., development pattern is similar for all, e.g., a baby cannot learn to walk before acquiring ability to sit and stand independently.
3. Attainment of new skills builds on achievement of earlier skills, i.e., skills are not skipped and if so happens, the advanced skills may represent deviant development pattern, e.g., three-four-word sentence in a child who does not follow commands and has limited vocabulary, may represent echolalia and suggest autism. Similarly, early hand preference before 18 months of age is abnormal and indicates paresis of the other upper limb.
4. Development proceeds in cephalocaudal direction, i.e., from head to toe. A child has to learn to hold his head before acquiring truncal and limb control and arm movements come under cortical control before leg movements.
5. Development follows proximodistal principle, i.e., from the center of the body outward. Accuracy in reaching, grasping, transferring and manipulation (proximal development) are achieved before infant can isolate and use the index finger to explore the object (distal development).
6. Though development follows a predictable sequence, it proceeds at different rates influenced continuously by intrinsic and extrinsic factors that produce individual variations and make each child's development unique, e.g., all children learn to sit and crawl before standing, but the age at which they do so is different.
7. Development in one field may not necessarily parallel development in other fields, termed *developmental dissociation*. In other words, development in one field may be more rapid than in another or there may be retardation in one particular field. Thus, normal development in one field does not automatically imply normal development in another field. For example, a child with hearing impairment will have delay in language but not in motor domains.

8. Development proceeds from general to specific. Responses to stimuli change from generalized reflexes involving the whole body as seen in the fetus and newborn to discreet voluntary actions that are under cortical control, e.g., a young infant responds to a stimulus by vocalizing, kicking and arm movements, whereas an older infant will just go for the object and grasp it or may say the specific word and smile.
9. Cognitive development proceeds from simple to complex tasks, e.g., a child learns to coo and babble before saying meaningful words.
10. Certain primitive reflexes have to be lost before achieving voluntary functions. For example, grasp reflex has to be lost before the infant can learn to reach for objects and grasp them. Similarly, asymmetrical tonic neck reflex has to go before the infant can roll from supine to prone, bring the hands to midline or reach for objects.  
Persistence of primitive reflexes beyond the age at which they should disappear predicts abnormal development.

## FACTORS AFFECTING DEVELOPMENT

Child development is a product of both biological inheritance (the inborn genetic endowment from biological parents' nature) and environmental factors (nurture). Which one is more important for development is a topic of debate. However, both are critical for healthy brain development. There is an active interplay between innate potential of the child (genetic and temperament) and the environment (both intrinsic and extrinsic—nutrition, infections, exposure to chemicals and toxins, trauma, social and cultural, etc.). This makes development of each child unique.

The concept of brain plasticity helps to understand the importance of environmental influences on development. Plasticity refers to the ability of brain to reorganize neural pathways based on environmental stimulation. At birth, a child's brain contains billions of neurons. After birth, synapses develop rapidly with each neuron developing an average 15,000 synapses by 3 years of age. Neuronal pruning causes preservation of synapses in frequently used pathways and atrophy of less used ones. Thus, environment, both positive and negative, has a direct effect on the brain.

The transactional model of development proposes that infants, caregivers and their environment determine the child's developmental and behavioral outcome. It holds that the child and the caregiving environment tend to alter each other mutually, i.e., biological factors affect child-rearing environment and in turn are affected by it. In the following section, we discuss various biological and environmental factors affecting child development.

### Intrinsic (Biological) Factors

#### *Temperament*

Temperament has a major influence on all aspects of development. It refers to style of child's behavioral and emotional response to a variety of situations. It is mainly determined by genetic factors but can be modified by environmental forces. Temperament of a child is apparent during early infancy and shows considerable stability over time. Temperament influences development as it determines the child's adaptation to the environment, his activity level, attention, distractibility, quality of mood and intensity of reaction. Conflict, stress and behavioral difficulties may arise when the child's temperament does not match with caregiver's expectations.

#### *Brain Dysfunction*

Normal development requires anatomically and functionally normal central nervous system (CNS) and pathways. A child with CNS malformation (e.g., neural tube defects, lissencephaly) is unlikely to have normal development. Abnormal development

may result not only from intrauterine/perinatal insults (e.g., intrauterine infections, perinatal asphyxia, exposure to drugs/teratogens, radiation), events occurring later in life during period of brain growth (e.g., meningitis, encephalitis, intracranial hemorrhage) may affect development.

### *Genetic and Chromosomal Abnormalities*

Both chromosomal and multiple/single gene disorders can affect development to varying extent. Down's syndrome causes varying degrees of intellectual disability apart from causing other multisystem involvement. Fragile X syndrome is a single gene disorder causing developmental disabilities. Many other developmental disorders are being recognized to be caused by polygenetic inheritance.

### *Defects of Vision and Hearing*

Defects in special senses of vision and hearing have profound effect on development, especially if impairment is severe. A child with visual impairment would not be able to explore the environment, affecting his cognitive development. A child with hearing impairment would not develop spoken language unless his impairment is corrected.

### *Gestational Age*

The incidence of developmental disabilities like cerebral palsy, especially spastic diplegia, sensorineural deafness, visual defects, mental subnormality, learning disorders is more in preterm infants. Postmature infants are also at high risk because of high incidence of fetal distress and hypoxia.

### *Chronic Illnesses*

Impact of chronic illnesses, like congenital heart disease, chronic kidney disease, is dependent on multiple complex factors. Need for repeated hospitalization, impact of illness on physical activity and nutritional status and altered focus of parent's attention affect development.

### *Nutrition*

Adequate nutrition including adequate proteins, vitamins and essential minerals has a profound positive effect on child development. Exclusive breastfeeding for first 4–6 months of life has been associated with better intelligence (IQ) and cognition in infants. Inadequate nutrition before birth and in first years of life can interfere with brain development and can lead to intellectual disability and learning disabilities. Children with failure to thrive and severe malnutrition function at a lower cognitive level. Iodine deficiency and iron deficiency anemia are long known to be associated with cognitive development. Recent evidences show that mild iron deficiency without anemia can also interfere with cognitive development.

### *Environmental Exposure to Toxins*

Exposure to environmental toxins, e.g., lead, mercury, arsenic can have long-lasting effect on growth and development. Children with lead toxicity have lower cognition and higher rate of behavior problems

### *Stress*

Early stress can affect brain function, learning and memory adversely and permanently. Children exposed to extreme stress in early years of life illness/death of family member, parental separation, disasters, household move are at greater risk of developing a variety of cognitive, behavioral and emotional problems later in life.

## Extrinsic (Environmental) Factors

### Parental Health Status

Parental health status, especially mental health, has a clear impact on child development. Children of depressed mothers have substantial delay in cognitive and language development.

### Parenting Style

Time and attention given to the child by parents play a major role in infant and toddler development. Warm, supportive, caring, encouraging and enriched stimulating environment encourages development. Children continue to practice skills if they are rewarded and their behavior is reinforced. Positive emotionality, sensitivity and responsiveness toward child and avoidance of harsh physical punishment facilitate social-emotional development. Parenting styles differ with respect to degree of nurturance and discipline. Parenting styles can be classified as *authoritarian* (high demands and low nurturance); *permissive* (low demands and high nurturance); or *authoritative* (firm but democratic style combined with high nurturance). Authoritative approach is most desirable and associated with optimum outcomes, where parents provide warmth and support to their children and allow children to have input in the decision-making process, although parents have the final say. Parenting style should be consistent, clear and fair across caregivers and across situations. Disorders of attachment may result from inconsistent caregiving.

### Family Environment

Families have a profound effect on a child's development, especially cognitive and language development. Interaction between the child and family and quality of interaction plays a major role in development. Abusive and aggressive household environment has long-term consequences on development and mental health. Young children exposed to violence show increased risk of behavioral problems, aggressiveness and reduced level of prosocial behavior.

### Sociocultural Environment

Culture refers to a society's total way of life including customs, traditions, beliefs, values and language which is passed on from parents to children. Cultural patterns influence composition of household, how members interact with each other and child-rearing practices, thus affecting development.

## Socioeconomic Status

Socioeconomic status (SES) combines several factors including income, education and occupation of parents. Factors associated with SES that affect development include amount of time spent by parents with children, parents' emotional status, nutrition, neighborhood environment, access to education and other opportunities. Young children of educated parents have higher level of cognition.

## IN A NUTSHELL

1. *Neurodevelopment* is a process of functional maturation related to maturation of the nervous system.
2. Developmental assessment should be a part of every comprehensive child evaluation.
3. Developmental milestones are organized into four domains for ease of assessment. However, they are all interrelated.
4. Development proceeds in a sequential, orderly and coherent pattern following certain laws that can be observed.
5. Attainment of one skill builds on attainment of earlier skills and skills are not skipped.
6. Development is a product of functional maturation of nervous system and learning. It is affected by various intrinsic (biological) and extrinsic (environmental) influences.
7. Developmental pediatrics is concerned not only with children with developmental disabilities but also contributes to the care of children who are developing normally and those who are at risk for developmental disorders because of medical conditions and adverse environment.

## Chapter 20.2

# Normal Development

Ujjwal Nene

Child development refers to the biological, psychological and emotional changes that occur in humans in the period between birth and the end of adolescence, as the individual progresses from dependency to increasing autonomy. It is a continuous process with a predictable sequence and yet it has a unique course for every child. Other processes such as social, moral and language development occur simultaneously in the course of development.

### THE FIRST YEAR

The newborn starts to learn through interacting with his environment and acquires competencies in all domains of development. Therefore, adequate interaction with caregivers and nutritional care play a crucial role in providing a *learning* experience to the infant. Normal development of the brain structure and effective functioning during infancy is normally an outcome of a healthy environment. Most of the child's understanding of his surroundings during this stage occurs through motor responses to the different sensations he receives. These early sensory-motor experiences influence the child's perceptual, cognitive and intellectual abilities. The parent-child relationship and quality of interactions form a foundation for further normal development.

### Motor Development

The first year of life is the stepping stone for achieving two major types of skills—gross motor and fine motor. Gross motor skills require the use of large muscles to achieve sitting, crawling and walking, jumping, kicking and running. These skills are normally achieved in the first two-and-a-half years to 3 years of age. Fine motor skills involve the use of small muscles in the hands and fingers in tasks such as picking up small objects, and later for feeding, writing, dressing, etc. Fine motor skills need practice and opportunities and continue to develop till the late ages. **Table 1** illustrates motor milestones achieved in the first year and the upper limits to achieve the same.

### Cognitive Development

According to Piaget, birth to 30 months is a period of sensory motor development. The child explores his environment and acquires various competencies using different senses in his waking state and is able to perceive objects and events as coherent.

A 2-month-old infant can differentiate between colors and patterns. Human facial expressions, such as *smile*, are successfully recognized at around the same age. Infants can match different properties in their surroundings, such as curvature, sequential, patterns and native versus nonnative rhythmic language patterns. They seek stimuli actively, integrating all the sensory inputs in the central nervous system and begin to use their innate reflexes. For example, grasping and sucking of objects are practiced as a way to stimulate and satisfy themselves. In this early stage of cognitive development, infants repeat and modify their actions that are focused on their own bodies to seek pleasure and satisfaction. For example, a baby may accidentally bring its finger close to its mouth and start sucking on it. On finding this behavior pleasurable, it will repeat this behavior over and over again. At around 2 months, the child starts smiling voluntarily with stable eye contact which significantly elevates the quality of the parent-child relationship and their bond of affection. A 3-month-old infant shows interest in people, plays with toys, kicks, bounces, reaches for his toes, watches his fingers move, and is attracted to very bright stimuli. A 4-month-old baby's close vision is well-established along with increased eye contact with parents and others. Its eye-hand coordination begins to develop, i.e., the child starts attempting to reach bright objects. Infants explore their own bodies, their surroundings and the people around. Their emerging sense of self helps them distinguish themselves from their mothers. They also start to tell their mothers apart from others and show preference to them as a source of satisfaction, affection and trust.

A 6-month-old infant shows more interest in manipulating, inspecting and exploring objects using all possible senses. Mouthing objects becomes the most prominent way of exploration. Transfer of object from one hand to another, visual inspection in sitting position, free hand and neck movements, voluntary grasp and release allow the child to experience the multisensory input of their surroundings. A safe and secure environment enables the child to master different behaviors.

**Table 1** Gross motor and fine motor milestones achieved during the first year

Milestones	Age	Gains/advantages	Upper limits to achieve the milestone
Neck hold and head control while in sitting posture	11 weeks	Allows visual observation, can follow moving objects more freely	21½ weeks
Pulls to sit with good head balance	13½ weeks	Adequate muscle tone allows child to proceed ahead	24 weeks
Rolls from back to stomach	18½ weeks	More body control and flexibility, motivation for locomotion	28 weeks
Sits alone with good coordination	23 weeks	Allows inspection visually, manipulation using both hands	30 weeks
Stands up on holding on to furniture	32 weeks	Coordinated movements of visual perception and locomotion	40 weeks
Walks independently	52 weeks	More self-control, exploration of surroundings, choice of proximity	61 weeks
<b>Fine motor development</b>			
Retains ring or rattle	14 weeks	Free play with objects	22 weeks
Reaches for toy	14½ weeks	Visuomotor coordination	22 weeks
Loses palmar grasp	20 weeks	Voluntary control on release	29 weeks
Transfers object hand-to-hand	21½ weeks	Exploration of movements and objects—visual and tactile	29½ weeks
Pat-a-cake, midline skill	35 weeks	Social play, grannies games	43 weeks
Turns pages of book	43 weeks	Increased visual observation for small details, autonomy for choice of stimulus	48 weeks

Acquisition of the concept of *object permanence* is a major milestone in cognitive development. The term was introduced by Jean Piaget to describe a child's ability to know that objects continue to exist even though they can no longer be seen or heard. A newborn focuses on objects in front of it only as a reflex activity. During 1–4 months, babies look at the spot for a long time from where an object disappears but do not visually or manually search for it. During 4–8 months, they search for partially hidden objects whereas by the age of 12 months, they search for completely hidden objects, i.e., toy hidden under a napkin. By 18 months, the child can find the object that he has seen being hidden but has difficulty if the object is displaced more than once. A 1-year-old likes to play *peek-a-boo* as an active play with caretakers. Children between 18 months and 24 months know that their parents exist even when not present, but cannot guess where they are and thus protest when separated.

### Language Development

Language development is the progressive growth in the ability to use language, from simple sound production to subsequent word fluency. Language development entails the maturation of a set of connected psychological processes including perception, cognition and memory as well as the biological maturation of the brain and those nervous system pathways that control the voluntary movements of the tongue and oral muscles. During the first 2 months, a child's language development can be observed by its ability to vocalize, recognition of its mother's voice, interest in and responses and smiles given to human talk. The first stage of language development is known as the prelinguistic, babbling or cooing stage, typically lasting from 3 months to 9 months of age when babies begin to make vowel sounds and by 5 months, they start producing consonant sounds too. By the end of 1 year, the child reaches the second stage—one-word or *holophrase* stage—the child tries to communicate its needs and wants effectively using a single word that stands for a sentence, i.e., water, mummy, etc.

### Emotional Development

An infant feels safe and secure only if trusted caretakers are consistently satisfying its emerging needs. This positive experience can develop a secure bond between parent and child which finally results in attachment. Erikson's first stage of psychosocial development, basic trust versus mistrust, completely depends on reciprocal attachment and maternal bonding. Parenting style and the child's temperament are two major factors that can significantly affect its emotional status. The infant's discomfort due to hunger that results in crying is alleviated by the parent who offers it food. This relief from distress is instrumental in developing an increased attachment and bond between the parent and child. The baby's emotions may be divided into two groups—pleasant or positive and unpleasant or negative. At birth, display of emotions is only through crying and screaming. During the sixth month, the baby can match emotions to others. During the ninth month, it starts showing negative emotions. At around 1 year, crying becomes a response to show dislike. Demand for autonomy emerges at this age that is manifested by throwing tantrums.

### Social Development

The first *social* relationship and feeling of attachment that most infants develop is with a parent and in most cultures that parent is the mother. A child's smile at seeing the mother's face is the beginning of social development. At around 3 months, the child regards his mirror image and at the fifth month, he enjoys playing with it. During the initial 6 months, the child shows interest in touching and looking at other infants and cries in response to the others crying. Through 6–12 months, the infant tries to influence

other infants by looking, touching, vocalizing, laughing or waving. Interactions with them are generally friendly, but they may hit or push one another.

**Table 2** provides the normal cognitive, language, emotional and social developmental milestones achieved during the first year and their approximate upper age limits.

### Implications of Delay in First Year

Delay in motor development can have major effects on the child's mental and social development. If the child fails to attain the expected milestones even after reaching the outer limit age, the pediatrician and parents should begin the required investigations and provide the child with adequate stimulation with the help of professionals, i.e., occupational therapists.

Babies kept in the neonatal intensive care unit (NICU) for a longer duration may face problems in their cognitive, social and emotional development due to deprivation or restricted mother-child interactions as well as the various NICU procedures. In such cases, the pediatrician should guide the parents regarding proactive preventive actions for dealing with the delay. Intervention in terms of multisensory stimulation, cognitive stimulation may be provided using the multidisciplinary approach. Infants left alone for a long duration, overexposure to television and mobiles are at risk of delayed social, emotional and language development. The child who does not respond to its own name should be observed carefully since it can be an early sign of autistic spectrum disorder.

## THE SECOND YEAR

Some of the important characteristics of the second year are an emerging sense of self, increased independence due to motor development and acquisition of primary communication skills. The child learns to organize its behavior through symbolic thinking and newly acquired skills in different areas.

### Motor Development

Most of the children start walking independently by the end of first year and latest by 15 months. A toddler's body proportion, i.e., its big head, short legs and big torso, makes its walk broad-based and unsteady with poor balance, with bent knees and arms flexed at the elbow. After few weeks of learning, the child's walk becomes noticeably refined. At 13–14 months, the child can walk backward and sideways. By the end of 15 months, it can climb up and down the steps with help and by the end of 22–23 months, independent climbing is achieved. Coordinated actions of running, watching and holding an object with adequate balance become easy.

### Cognitive Development

In this stage of tertiary circular reactions, the child becomes highly curious about its surroundings. This leads to experimentation with various external objects and trial and error is used vastly to understand the different properties of these objects. For example, children drop objects deliberately as they are fascinated to see what happens. Such exploration is an early form of problem-solving. By 18 months, the concept of *object permanence* is ingrained and this helps them understand their surroundings better and develop an imagination. The cognitive changes at 18 months are strongly associated with important changes in the emotional and language domains. Parallel development of fine motor movements, improved dexterity and development in language and communication help enhance the child's cognitive abilities which become evident in the child's behavior. For example, a 2-year-old child can match circles on a board game, can draw shapes such as lines on paper that stand for real objects such as a curved line for a flower, etc. Make believe play activities (symbolic play), mainly with their own bodies, become prominent at this stage, e.g., bathing or feeding the doll.

**Table 2** Normal cognitive, language, emotional and social development during the first year and their \*upper limits (in parentheses)

Age in months	Cognitive development	Language development	Emotional development	Social development
1 month	Momentary regard of object Visually follows moving objects Searches with eyes for sound	Expresses distress by crying	Cries Becomes quiet in response to auditory or tactile stimuli	Shows interest in human talk
2 months	Recognizes mother visually (13 weeks) Differentiates between familiar and unfamiliar stimuli Reaches for dangling ring/object, carries to mouth (17 weeks)	Babbles Coos Vocalizes two syllables (13 weeks)	Shows distress, excitements and pleasure	Smiles when mother touches, talks Gives social smile to face-to-face talk—other than mother (13 weeks)
3 months	Follows vanishing object/persons (17½ weeks) Turns head to sound of bell/rattle (19 weeks) Manipulates/starts simple play with toys (19 weeks) Stares at own hands (20 weeks)	Responds to talk using sounds	Can match facial emotions such as pleasure and distress with adults	Becomes more friendly with caregivers
4 Months	Engages in explorative play with paper or sound-making objects (20½ weeks)	Increased vocalization	Continues expressing emotions from simple to complex in progressive manner	Discriminates between caregivers and strangers (26 weeks)
5 months	Reaches for cube, objects (22½ weeks) Sustains inspection of red ring (24½ weeks) Eye cooperation in reaching and picking up object (20½ weeks) Lifts a cup by handle (20½ weeks) Persists in reaching objects (24½ weeks) Shows high interest in banging as a play (24½ weeks) Transfers object hand-to-hand (28½ weeks)	Shows discomfort or comfort through vocalizing, smiling (23 weeks) Shows interest in sound production (24½ weeks)	Exhibits primitive resistant behavior Turns head to show dislikes	Smiles to mirror image of self (24½ weeks)
6 months	Uncovers hidden toy (36 weeks) Manipulates objects—shows interest in details (28½ weeks) Pulls string adaptively and secures toy (32 weeks)	Vocalization of different syllables (32½ weeks) Listens selectively to familiar words, recognizes names of close family members and familiar objects (36 weeks)	Expresses anxiety, discomfort in strangers company Can respond to and express range of emotions, i.e., excitement, anger, fear, joy, interest Smiles and laughs when the mother does so	Shows more attachment to familiar adults
7 months	Uses thumb opposition for objects hold (30 weeks) Actively manipulates objects with eye-hand coordination (30 weeks)	Babbles in a complex manner mixed with few syllables (35 weeks)	Responds to vocal tone, shows resistance. Displays fear, anger, defiance, affection and shyness	Shows interest in interacting with caregivers and in simple play (32 weeks)
8 months	Looks at pictures in books (40 weeks) Looks for disappeared contents of box (44 weeks)	Says <i>da-da</i> , <i>ba-ba</i> or equivalent (36 weeks)		
9 months	Plays pat-a-cake, achieves midline skill (40 weeks)	Recognizes native language (36¾ weeks)	Shows anxiety and distress when separated from parents	Enjoys games with series of actions with adults
10 months	Holds crayons adaptively, attempts scribbling (45 weeks)	Starts using expressive gestures (45 weeks) Inhibits on verbal command <i>no</i> (45 weeks)	Frowns when annoyed and shows a fear of strangers	Imitates simple actions like combing, patting, etc.
11 months	Turns pages of books (45 weeks) Unwraps cover and secures object hidden in front of child (45 weeks)	Follow simple commands such as put, give (52 weeks) Imitates words (57 weeks)	Expresses likes and dislikes using sounds, gestures and facial expressions	Enjoys interacting with other children and adults Enjoys imitative play, imitates simple actions
1 year		Uses particular words for needs and demands	Throwing tantrums for demands Becomes distressed when others are distressed	

\*Upper limits are derived from *Developmental Assessment Scales of Indian Infants* developed by Dr Pramila Phatak (1998) that gives most precise estimation about development.

## Emotional Development

Family environment plays an important role in the child's emotional world. A stressful atmosphere at home makes the child feel vulnerable, insecure and anxious. Irritability, anger, problems related to feeding and sleep can be manifestations of internal anxiety and fear. Temper tantrums are often results of conflicts between parental control and the infant's need for autonomy and mastery over its actions. Fear responses are usually associated with the fear of loud noises or falling. Fear, rage and love are the basis for many other emotional responses. A one-and-a-half-year-old child can show shame, shyness and can express dislike through restlessness and tantrums. The child develops a preference for soft objects, i.e., stuffed toys, blankets for soothing, etc. At around 21 months, the child attempts to control those emotions that are not approved by its parents and tries to gauge its parent's feelings in order to behave accordingly.

## Language Development

In this domain, receptive language is achieved first, followed by expressive language, during the second year of life. 1-year-old children use *one-word expressions* but their understanding of language far exceeds their capacity to express themselves. An average 15-month-old child can show body parts, objects like shoes, watches, fans, etc. The rapid increase in vocabulary is typically found at about 18 months, when a child learns about 50 words. A dramatic change in the child's linguistic development occurs typically when it realizes that words (labels) stand for things. As a result, by 2 years of age, the average child knows about 900 words. A 2-year-old can follow two-step commands such as *sit-down here and drink water*. Increased use of language gives them a sense of control over their surroundings. **Table 3** provides a list of achievements to be checked by the pediatricians.

## PRESCHOOL PERIOD: 2–5 YEARS

The most drastic change in a preschooler's personal life is the separation from parents. At this age, the child acquires a good amount of control in the areas of language and communication. He is exposed to a larger world where he learns to behave as per the rules of society and school and tries to fulfill the different expectations of people and situations. The child learns to spend time away from parents, begins to enjoy the company of his age mates and becomes aware of his ability to utilize his resources as and when they are needed. Major check points at 3, 4, and 5 years of age are listed in **Table 4**.

## Motor Development

Normally, most of the 2 years and 4 months old children can raise themselves to the standing position from supine without turning to a side. They can build a tower of 8 cubes, hold a pencil in fingers with the opposable thumb, jump with both feet, and walk on tip-toe when asked and fold paper after demonstration. As they approach 3 years, they learn to walk with good coordination and a mature gait and can even run. Various motor actions are acquired successfully, such as kicking, catching, throwing, dancing, climbing on structures, etc. At 3 years, they can dress and undress themselves with a little help in buttoning. Bedwetting is normal up to the age of four in girls and five in boys. Handedness is normally established by the third year, though hand dominance is often observed at around 2 years itself.

## Cognitive Development

The period between 2 years and 7 years was labeled as preoperational stage by Piaget, which is characterized by perception-dominated thinking, egocentrism, and magical thinking. Inanimate objects are given life, e.g., a doll talks to the

**Table 3** Developmental check-points at 18th and 24th months

18 months	24 months
Walks independently	Climbs up and down the stairs with hand held
Throws a small ball	Builds tower of three cubes
Responds to word or command with appropriate actions	Combines two words like <i>go-out</i> , <i>me-ice cream</i>
Understands inhibiting verbal commands	Understands and follows simple verbal instructions

Data are derived from Developmental Assessment Scales of Indian Infants which offers the most precise estimates of developmental level.

**Table 4** Developmental check-points at 3rd, 4th and 5th years

3-year milestones	4-year milestones	5-year milestones
Runs forward well	Copies a cross	Swings, hops, somersaults
Turns single page of book	Walks down stairs like adult without support	Says name and address
Makes a circle, vertical and horizontal line	Uses plural	Defines objects of daily use verbally
Strings beads	Cooperates with other children	Draws a square
Gives full name, names common pictures and things	Gives opposites of simple adjectives	Counts ten or more objects
Identifies pictures by their descriptions	Matches shapes, animals, colors	Likes to sing and dance
Understands basic color concept of black and white		

Data are derived from Stanford-Binet test, and other scales that offer the most precise estimates of developmental level.

child, plants feel pain when flowers are plucked. They find it difficult to understand the cause and effect relationship as true logical thinking develops at a later stage. Now there is a beginning of abstraction, e.g., a wedding is a representation of meeting relatives or eating sweets.

Normally, a 30-month-old baby can point to seven pictures, name objects and pictures, understand the concept of 1, which is the beginning of arithmetical thought. Similarly, awareness about the human body often develops by 30 months. A 3-year-old child can differentiate between big and small, more and less, understanding of body parts and their functions. A 5-year-old can define objects verbally by their uses, draw a square, and understand similarities and differences on a concrete level.

## Language Development
